Principles and Practice of Geriatric Psychiatry.
Editors: Professor John R. M. Copeland, Dr Mohammed T. Abou-Saleh and Professor Dan G. Blazer

Print ISBN 0-471-98197-4 Online ISBN 0-470-84641-0

Preface

The editors were very gratified that the first edition of this textbook was generally well received and that a second edition has been called for. It is now seven years since the original book appeared, and there have been many more advances in the subject. In spite of new sections and some wholesale rewriting, it has been possible once again, to contain the information in one volume. Very sadly some of our original contributors have died. New authors have replaced them while others have been added in an endeavour to keep the text authoritative and up-to-date. The helpful criticisms of the first edition have been carefully considered in the preparation of this one. Having so many distinguished authors with such a breadth of interest, while greatly enhancing the book, has led to a long gestation period, but we believe that it has been worthwhile. Much of the original format has been retained in order to continue to stimulate lively debate and exchange of views. If the book contributes to the growing strength of Geriatric Psychiatry internationally, it will have done its work.

Preface to First Edition

The discipline of the psychiatry of old age has moved rapidly in recent years and the number of practitioners has expanded world-wide. An authoritative text is required which draws on the knowledge of these experts and which reflects both new scientific advances and innovations in service development.

In a comparatively new subject many of the issues are still contentious and on some of these we have tried to provide the opportunity for the expression of different points of view. Readers are asked to judge the issues for themselves from the evidence set out.

Here and there short, special articles have been commissioned which present research findings in more detail and describe new aspects of care. They are intended to enliven the text and their choice has been dependent on timing and opportunity.

We have also tried to give a ''feel'' for what is happening in developing countries and the scope of the problems experienced by local practitioners.

Even a book of this size can never be complete and no doubt gaps in the coverage of subjects will be identified. We would be glad to have them pointed out. The more comprehensive a book aims to be the longer it takes to come to publication and in a fast-moving area of knowledge this can be a problem. Many of our authors have been kind enough to update their contributions at a late stage, which we hope has overcome this difficulty to some extent.

In the early stages of the development of a subject there is insufficient corpus of knowledge to assemble in book form. This situation has changed dramatically for geriatric psychiatry in recent years. We hope that the knowledge gathered here from our distinguished international panel of authors bears this out.

A Conceptual History in the Nineteenth Century

G. E. Berrios

Department of Psychiatry, Addenbrooke's Hospital, Cambridge, UK

The history of geriatric psychiatry can be written from two viewpoints. The "externalist" approach focuses on the social and political variables that have controlled attitudes towards abnormal behaviour in old age, and on the professionalization of those charged with the care of the mentally infirm elderly. The "internalist" approach—to be followed in this chapter—concentrates on the origin of the scientific language of psychogeriatrics. An adequate historical account should include information on theories of ageing, both physical and mental, brain sclerosis and the formation of a viable concept of mental illness. On the first rubric much research has been done[1–9]; far less work exists on the other two. On psychogeriatric care before the nineteenth century[10,11] there is very little: this may simply reflect a historical reality.

VIEWS ON AGEING BEFORE THE NINETEENTH CENTURY

Like most other aspects of human life, ageing has also been portrayed in terms of metaphors. Classical views, following the nature—nurture controversy, conceived of ageing as resulting from either internal instructions or from the buffeting of foreign factors[4,8].

The "wear and tear" view happened to be popular during the early nineteenth century, the period on which this chapter will concentrate. It was based, as it had always been, on the ageless observation that all natural objects, whether animate or not, are subject to the ravages of time. Surprisingly enough, the "wear and tear" view has not always generated an understanding attitude. In fact, across times and cultures great ambiguity has existed in regard to the treatment of old folk. Fortunately, a realistic acceptance seems to have predominated although there is plenty of evidence of hostility. The Hebrew tradition, and indeed its Christian offshoot, encouraged much reverence towards the wisdom and value of old age. But even in societies which have made great play of this view, veneration has been reserved for those in positions of power or influence[12]. Little is known about attitudes towards elderly women or old men in humbler stations[11].

So, it can be concluded that, all in all, a view seems to have predominated that ageing was undesirable and that the identification of wear factors was important to devising ways of prolonging life[5,13].

A second ambiguity can be detected in these earlier writings. It concerns the extent to which the ageing process necessarily involves the human mind. Whilst it was a palpable fact that all human frames decayed, not everyone accepted that this had necessarily to affect the soul or mind. Extant descriptions of the psychological changes brought about by old age suggest that people were aware that the mind also underwent a decline. However, theory and religion encouraged the view that the spirit could or did escape wear and tear, and that human beings grew ever more wise and useful, thanks to the accumulation of experience and knowledge. This belief must have been available in all those societies that felt the need to create adequate spaces for all manner of intellectual and/or sociopolitical gerontocracies[2]. Some seem even to have separated chronological age and functional age in order to justify such concessions. From the point of view of the history of psychogeriatrics, it would be useful to know to what extent this belief was undermined by the occasional case of dementia amongst those elderly in positions of power[1]. Historical evidence seems to show that these situations were neither more nor less perturbing than mental illness occurring at other periods of life. Indeed, fail-safe devices seem to have been available in these societies to cope with the upheavals created by such occurrences.

Men like Buffon, Darwin and Goethe reshaped ideas on ageing during the eighteenth century. Buffon[14] wrote: "All changes and dies in Nature. As soon as it reaches its point of perfection it begins to decay. At first this is subtle and it takes years for one to realise that major changes have in fact taken place" (p. 106). Buffon put this down to an "ossification" process similar to that affecting trees: "this cause of death is common to animals and vegetables. Oaks die as their core becomes so hard that they can no longer feed. They trap humidity, and this eventually makes them rot away" (p. 111).

Erasmus Darwin's views resulted from the application of yet another metaphor, namely, that ageing results from a breakdown of "communication" between man and his environment[15]. Darwin suggested that such breakdown followed a loss of irritability (a property of nerve fibres) and a decreased response to sensation:

> "It seems our bodies by long habit cease to obey the stimulus of the aliment, which support us . . . three causes may conspire to render our nerves less excitable: 1. If a stimulus be greater than natural, it produces too great an exertion of the stimulated organ, and in consequence exhausts the spirit of animation; and the moving organ ceases to act, even though the stimulus is continued. 2. If excitations weaker than natural be applied, so as not to excite the organ into action, they may be gradually increased, without exciting the organ into action, which will thus acquire a habit of disobedience to the stimulus. 3. When irritative motions continue to be produced in consequence of stimulus, but are not succeeded by sensation . . ." (p. 365).

VIEWS ON AGEING DURING THE NINETEENTH CENTURY

In 1807 Sir John Sinclair[16] published a major compendium on ageing and longevity which included references to most pre-nineteenth century sources. It was, in a way, the last grand glance to the past. Soon afterwards work started by those who, like Léon Rostan (1791–1866), based their claims on empirical findings. Rostan, one of the most original members of the Paris school, published in 1819 his *Recherches sur le Ramollissement du Cerveau*[17], where the view commenced that vascular disorders might be as important as parenchymal ones in brain ageing. Even more important was his uncompromising anti-vitalistic position enshrined in the claim that all diseases were related to pathological changes in specific organs[18,19].

During the 1850s Reveillé-Parise[3] saw his task as writing on "the history of ageing, that is, mapping the imprint of time on the human body, whether on its organs or on its spiritual essence" (p. v). In regard to ageing itself he wrote: "the cause of ageing is a gradual increase in the work of decomposition . . . but how does it happen? What are the laws that control the degradation that affects the organization and mind of man?" (p. 13). Reveillé-Parise dismissed the toxic view defended by the Italian writer Michel Lévy[20] according to which there was a gradual accumulation of calcium phosphates that led to petrification, to an "anticipation of the grave". This view, he stated, had no empirical foundation and was based on a generalization from localized findings. Reveillé-Parise supported the view that ageing results from a negative balance between composition and elimination which equally affected the cardiovascular, respiratory and reproductive organs.

Finally, the views should be mentioned of J. M. Charcot, who in 1868 offered a series of 24 lectures on the diseases affecting the elderly[21]. Charcot dedicated Lecture 1 to the "general characters of senile pathology"; he started by saying that all books on geriatrics up to his time had "a particularly literary or philosophical turn [and had been] more or less ingenious paraphrases of the famous treatise De Senectute" (p. 25). He praised Rostan for his views on asthma and brain softening in the elderly, and predictably also mentioned Cruveilhier, Hourman and Dechambre, Durand-Fardel and Prus. He criticized Canstatt and other German physicians because in their work, "imagination holds an immense place at the expense of impartial and positive observation" (p. 26). Charcot's own contribution was based on the general principle that "changes of texture impressed on the organism by old age sometimes become so marked, that the physiological and pathological states seem to merge into one another by insensible transitions, *and cannot be clearly distinguished*" (p. 27).

THE DEVELOPMENT OF THE NOTION OF BRAIN SCLEROSIS

When in 1833 Lobstein[22] described the basic pathology of arteriosclerosis, he did not imagine that it would, during the second half of the century, become the mechanism of "senility" *par excellence*[14,23,24]. Motor and sensory deficits, vertigo, delusions, hallucinations and volitional, cognitive and affective disorder were all attributed to the effect of arteriosclerosis[25,26]. They related to the brain via a two-stage speculative pathophysiology: parenchymal and/or vascular disorders could affect the brain, and the distribution of the lesions could be diffused or focal. Vascular changes included acute ischaemia (on which clinical observation was adequate)[27,28] and chronic ischaemia, invented as a separate syndrome by extrapolating from the symptoms and signs observed during the acute states[24]. The role of arteriosclerosis as a causal and prognostic factor in relation to the involutional psychoses was challenged early in the twentieth century[29] but this paper remained unnoticed. Hence, some of the old notions, such as that of "arteriosclerotic dementia", remained active well into the 1960s[30].

Alienists during the same period, however, were already able to distinguish between states where a putative chronic and diffuse reduction in blood supply had taken place from focalized damage, i.e. what they called "multifocal arteriosclerotic dementia" and was equivalent to what is currently called multi-infarct dementia[24,31,32].

NINETEENTH CENTURY VIEWS ON MENTAL DECAY IN THE ELDERLY

It is against this background that the history of the language and concepts dedicated to understanding mental disorders in the elderly must be understood. In addition to these neurobiological frameworks, a psychological theory that explained the manner of the decline was required. Such a psychopathology was provided by the heuristic combination of associationism, faculty psychology[33], and statistics[34] that characterized the early and middle part of the nineteenth century.

Yet another perspective, originating in clinical observation, was added during the 1830s. It led to the realization that, in addition to the well known forms of mental disorder, the elderly might exhibit specific forms of deterioration, and that these could be related to recognizable brain changes. There is only space in this chapter to deal with two examples: one typifying a "specific" disorder of old age, namely the history of chronic cognitive failure or dementia; the other illustrating the effect of a general mental disorder (melancholia) on the elderly.

THE FORMATION OF THE CONCEPT OF SENILE DEMENTIA

The history of the word and concept of dementia before the nineteenth century has been touched upon elsewhere[35]. Suffice it to say here that, at the beginning of the last century, "dementia" had a "legal" and a "medical" meaning and referred to most acquired states of intellectual dysfunction that resulted in serious psychosocial incompetence. Neither age of acquisition nor reversibility was part of its definition. These two dimensions were only incorporated during the nineteenth century and completely changed the semantic territory of the dementia concept.

Anecdotal observation of cases of senile dementia abound both in the fictional literature and in historical documents[36], but the concept of "senile dementia", as it is currently understood, only took shape during the latter part of the nineteenth century. Indeed, it could not have been otherwise, as the neurobiological and clinical language that made it possible only became available during this period[37,38]. But even after the nosological status of senile dementia had become clearer, there were many who, like Rauzier[39], felt able to state: "it may appear either as a primary state or follow most of the mental disorders affecting the elderly" (p. 615). Following Rogues de Fursac[40], Adrien Pic—the author of one of the most influential geriatric manuals during this period[41]—defined senile dementia as: "a state of intellectual decline, whether or not accompanied by delusions, that results from brain lesions associated with ageing" (pp. 364–365). It was against this background that the concept of Alzheimer's disease, which became the prototype for all senile dementias, was created during the first decade of the twentieth century[37]. Recent work has shown that its "discovery" was controlled by ideological forces well beyond what could be described as "scientific"[37,42]. These

forces also introduced unwarranted clinical strictures, such as the exclusion of non-cognitive symptoms[43,44] and false age boundaries, which took many years to disappear.

THE FORMATION OF THE CONCEPT OF INVOLUTIONAL MELANCHOLIA

The concept of "senile or involutional psychoses", which featured so prominently in Kraepelin's early classification, included: presenile delusional insanity, senile dementia, late catatonia and involutional melancholia[45,46]. The reasons that led Kraepelin to separate this group were mostly theoretical, to wit, that they appeared during a period of life when "sclerotic" changes were beginning to occur; the same factor accounted for their bad prognosis[46].

The general history of melancholia and depression has been analysed elsewhere[47–49]. Suffice it to say here that by the 1860s depression was considered to be an independent syndrome resulting from a primary disorder of affect. This meant that hallucinations, delusions and cognitive impairment were secondary to the pathological feelings. This conviction was particularly strong towards the end of the century, when emotional mechanisms became popular in the explanation of most forms of mental disorder[50]. By the end of the century the metaphor of depression as a form of "reduction" or "loss" had become firmly established. No better example can be found than the fact that up to 1893 (fourth edition) Kraepelin felt obliged to classify all forms of agitated depression as mania![51].

KRAEPELIN AND INVOLUTIONAL MELANCHOLIA

Much of the current confusion on the meaning of involutional melancholia can be explained if attention is given to the circumstances of its historical development (for a full analysis of this process and list of references, see reference 52). The conventional story[53–56] is that up to the seventh edition of his textbook Kraepelin considered involutional melancholia as a separate disease, and that when confronted by the evidence collected by Dreyfus[57], he decided to include it, in the eighth edition, under the general heading of manic depressive insanity. Indeed, this account was first offered by Kraepelin himself (see reference 57, p. 169).

The story is, however, more complex and it is unlikely that the findings of Dreyfus alone caused Kraepelin's change of heart. For example, Thalbitzer[58] claimed that his own work had also been influential (p. 41). In the eighth edition Kraepelin abandoned not only involutional melancholia but the entire group of "senile psychoses". A recent statistical analysis of Dreyfus's old series has also shown that his conclusion that the natural history of involutional melancholia was no different from that of depression affecting younger subjects was wrong[51].

CONCLUSIONS

This short chapter, providing a historical vignette on the origin of the language of old age psychiatry, suggests that it was born during the nineteenth century from three conceptual sources: theories of ageing, neurobiological hypotheses concerning brain sclerosis, and the realization that specific forms of mental disorder might affect the elderly. Two clinical illustrations were provided, one pertaining to the origins of the concept of senile dementia, and the other to the notion of involutional melancholia.

Scope and Development in the Twentieth Century

Ewald W. Busse
Duke University Medical Center, Durham, NC, USA

Interest in the health and well-being of the elderly has existed since antiquity; over the centuries some remarkable observations were made regarding the health, the mental changes, and the care of the elderly. Some explanations were offered for age changes that were reasonable and some were fanciful, limited by existing scientific knowledge[1]. During the twentieth century, many biological and behavioral theories of aging have been advanced and tested, emphasizing that aging is a multidimensional phenomenon.

To understand the rapid emergence of the psychiatry of old age during the twentieth century, one must appreciate that around the year 1900, the age composition of the population began to change. Life expectancies for both males and females were being extended, particularly for females. This was paralleled by a rapid expansion in science and technology.

Although the term "gerontology" has been around for many years, the term "geriatrics" was not coined until 1914 by Nascher. In that year he published the book *Geriatrics. The Diseases of Old Age and Their Treatment*[2]. A prolific writer, Nascher's last publication in 1944 was *The Aging Mind*[3]. He observed that chronic brain syndrome was likely to be familial and he believed that it was an accelerated primary aging process that was influenced by heredity. Seven years prior to Nascher, Alzheimer published his landmark report, which described what is now known as Alzheimer's disease and is sometimes referred to as "the disease of the century"[4]. In the 1960s, books on aging and psychiatry began to appear. Among the best known of those in the English language were *The Clinical Psychiatry of Late Life*[5] by Felix Post and *Behavior and Adaptation in Late Life*[6]. In the ensuing years, many important publications have appeared that reflect rapid advances in scientific knowledge and clinical practice. In the 1940s, gerontological and geriatric societies were organized in many countries in Europe and in North America. Early in 1950 the International Association of Gerontology was founded in London, UK, with the support of the Nuffield Foundation. The first international congress of gerontology was held in Liège, Belgium, July 9–12, 1950[7]. The International Psychogeriatric Association was founded in 1980 and held its first meeting in Cairo in 1982[8].

GERIATRIC MEDICINE AND GERIATRIC PSYCHIATRY

For the past several decades, psychiatry and geriatrics have been experiencing what is called by many an "identity crisis"[9]. This crisis in identity centers on the sphere of professional activity that is the proper task of psychiatrists and geriatricians and whether their activity produces a source of self-esteem to the physicians. The geriatric psychiatrist is making a significant contribution to solving this so-called identity crisis. The geriatric psychiatrist must often function as a primary care physician and his/her skills include proficiency in psychiatry, geriatric medicine, neurology and the social sciences. Geriatric psychiatrists are very aware that many of the disorders they treat can be cured or prevented but the resulting suffering can be relieved and the disability reduced. The situation does encourage the clinician to make observations that contribute to a better understanding of the course of chronic illness and to look for hidden clues that can lead to investigations which may, in the future, bring improved convalescence or even eradication of chronic disease and disability.

TECHNOLOGY

Advances in technology have widened the scope of old age psychiatry. For example, biochemical changes in the brain are distorted by the dying process and postmortem events. Routine postmortem examinations have limited usefulness, although rapid autopsies have improved the situation. *In vivo* brain imaging has enhanced our ability to observe biochemical processes and alterations in the aging brain[10].

PSYCHOPHARMACOLOGICAL APPROACH

The psychopharmacological approach is currently the dominant treatment for mental and emotional symptoms in elderly people. Psychotropic medications often reduce or eliminate symptoms, but do not alter the cause of the disorder. Consequently, very critically needed and exciting opportunities for research lie ahead for the geriatric psychiatrist.

Because of the possible multiple etiology of many psychiatric disorders of late life, it is highly likely that the geriatric psychiatrist will have to have a broad knowledge base and therapeutic skills including the use of medications, psychotherapeutic techniques, and procedures to reduce risks inherent in the socioeconomic status and environment.

PSYCHOTHERAPY

It is unfortunate that in 1905 Freud expressed the view that patients "near or above the fifties" were not suitable subjects for psychoanalysis[11]. For many years, this undoubtedly affected therapists' attitudes towards all psychotherapy for the elderly. Fortunately, a number of prominent psychoanalysts challenged

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

this Freudian view and reported psychotherapeutic success with older patients[12]. Beginning in the mid-twentieth century, a number of psychotherapeutic techniques were described and clinically evaluated for their effectiveness. Some are particularly applicable to the elderly psychiatric patient and include both behavioral and cognitive forms of psychotherapy. In Europe and North America psychotherapeutic approaches have been successfully used for elderly outpatients with depression and/or hypochondriasis.

THE SUBSPECIALTY OF GERIATRIC PSYCHIATRY

Geriatric consultants have served in the National Health Service in the UK for many years. A geriatric consultant is not a primary care physician and sees patients by referral, usually from general practitioners[13]. The geriatric consultant is likely to be hospital-based. Psychogeriatric long-term care beds are increasing in number and the responsibility is usually assigned to a consultant psychiatrist specializing in the psychiatry of old age. In 1985, the Royal College of Physicians of London conducted their first examination of candidates for a diploma in geriatric medicine. Although the Board of Examiners of the College includes representatives from general practice and from psychogeriatrics, the future of old age psychiatry as an area of specialization in the UK remains uncertain. In 1989 the British Department of Health recognized psychogeriatrics as an official subspecialty.

In Canada, the Royal College of Physicians and Surgeons in 1981 conducted examinations for special competence in geriatric medicine. Although geriatric psychiatry is not recognized as a subspecialty, the College has encouraged the development of programs in geriatric psychiatry. Since 1988 in the USA, the American Board of Internal Medicine, in collaboration with the American Board of Family Practice, has offered by examination a certificate of added qualifications in geriatrics. The examination is administered to candidates from both Boards at the same time in the same testing centers and the criteria for qualification are identical for both Boards[14].

Geriatric psychiatry was the first subspecialty area for which the American Board of Psychiatry and Neurology offered an examination for added qualifications. The first examination was given in April 1991 to 661 candidates and the second year to 578 candidates. Since the first examination 3435 certificates have been issued[15]. The next examination was scheduled for the year 2000 and the first re-certification in 2000 as well. All added qualifications in geriatric psychiatry will be time-limited to 10 years. In most European countries an examination is not required for qualification in a medical specialty. However, Sweden is moving to the examination as a requirement.

Recently there has been a rapid development of professional organizations concerned with geriatric psychiatry. Two of the most active are the American Association of Geriatric Psychiatry and the International Association of Geriatric Psychiatry. The American association has made available geriatric psychiatry self-assessment.

For many years, it was believed that many physicians are reluctant to become involved in geriatrics. Numerous explanations have been offered, including relatively low monetary compensation, the lack of satisfactory treatment outcomes and lack of personal satisfaction and scientific challenge[16]. This view has rapidly changed and considerable interest and satisfaction is evident among medical students as well as physicians in training and practice. A recent study of those who completed geriatric fellowships in geriatric medicine or psychiatry and have now been in practice for at least 3 years found that 93% were satisfied with their career choice, 80% felt that they had maintained professional status and prestige, 71% were satisfied with their incomes and 96% found personal gratification in taking care of elderly patients[17].

The Development in Britain

Tom Arie

University of Nottingham, UK

Psychogeriatrics, the psychiatry of old age, was born as a service activity some 25 years ago; in 1989 it became an official specialty in the National Health Service (NHS). Until the 1960s interest in the mental disorders of old age had been largely confined to research, but today special psychiatric services for old people are widely established, and the care of mentally ill old people is recognized as a major issue by professional workers, governments and the lay public, not only in developed countries but also in the Third World. Britain has led this movement.

ORIGINS

At the end of the 1960s, about half-a-dozen psychiatrists were running psychogeriatric services. Now there are some 450 and most health districts have such a service[1]. This movement has the backing of government and of the relevant professional and voluntary bodies. The origins of this service specialty are five-fold:

1. Pressure of the increase in the numbers of the aged, particularly of the very aged.
2. Growth in psychiatry's capacity to treat conditions previously regarded as hopeless[2].
3. The movement of psychiatry from mental hospitals into people's homes, and into the general hospital.
4. The effectiveness of geriatrics in British medicine.
5. The writings and teaching in the 1960s of a small group of figures such as Sir Martin Roth and David Kay in Newcastle, Felix Post in London, and the pathologist Nicholas Corsellis at Runwell, on epidemiology[3], clinical features and prognosis[4–6] and pathology of the mental disorders of old age[7].

In 1966 a paper from Newcastle[8] emphasized the intertwining of physical, mental and social factors in the psychosyndromes of old age, and called for general hospital facilities for collaborative assessment of these complex disorders. Other writers were concerned with the possibly damaging effects of "misplacement" of old people in units of the "wrong" specialty, and Duncan Macmillan, a great psychiatric innovator, with his colleagues set up an early assessment unit and took a special interest in the assessment and care of old people[9,10].

THE PSYCHOGERIATRIC MOVEMENT

A symposium at the end of the 1960s[11] stands as a statement of what had then been achieved, and of the directions in which people were looking. Half-a-dozen younger psychiatrists were meeting as a "coffee house group", sharing their experiences of setting up local services. They established contacts with government and with national bodies and they wrote, lobbied and spoke at innumerable meetings. Above all, they influenced younger colleagues[12].

In 1973 they formed a Group within the Royal College of Psychiatrists and in 1978, as numbers grew, the Group achieved the status of a Specialist Section. The Section has provided guidance on development of services, norms for staff and facilities and advice on changing issues. Successive chairmen of the Section have reflected the development of the specialty through three "generations" of workers.

By 1985–1986 some 250 psychiatrists were running local psychiatric services specifically for the aged[13], in a variety of different styles but with a common philosophy; there have been many reports describing such services (reviewed in ref. 14). Currently, it is likely that some 450 consultant psychiatrists are primarily engaged in this work.

From the late 1970s, international networks were established, both personally and through bodies such as the World Health Organization, the Geriatric Psychiatry Section of the World Psychiatric Association, and the International Psychogeriatric Association. For a decade a course on psychogeriatrics has been run in Nottingham for the British Council, with participants from over 30 countries; versions of this have been "exported" to Australia, Israel, Poland and Portugal. An apparatus of education is established, and the Royal College of Psychiatrists sets standards for training. There are full professors of psychogeriatrics at some seven UK universities and academic posts are established in most medical schools.

A TYPICAL SERVICE

Principles for providing such services, and accounts of resources needed, have been the subject of publications by individual workers, by the Royal College of Psychiatrists and by the government (reviewed in ref. 14). *The Rising Tide* from the NHS Health Advisory Service[15] has also been influential.

Developments have generally been around a group of core workers and facilities, the latter often determined by what happened to be available in the locality. One, and preferably two, psychiatrists will have special responsibility for the aged, working with nursing (including community nursing), remedial, social services, psychology and housing department staff, and with family doctors and their teams, with geriatric medical services and with voluntary and private facilities. The service generally deals with all forms of mental illness in old age, of which the commonest is depression, and the most exacting is dementia; but old age psychiatry spans virtually the whole of psychiatry—few problems

abate with age, and many become more intricate, with the admixture of physical and social problems.

The main thrust of a service is to maintain function, independence and choice. Staff strive to bring services to people in their homes, but hospital admission must be available for those who need it, as must a consultative service for other departments. Most services see patients initially at home and much follow-up takes place there or in the day hospital. Many units run special services, such as "memory clinics" or relatives' support groups, or collaborate in running stroke, continence or "orthogeriatric" services.

Standard facilities comprise an admission unit, which should be in the district hospital, outpatient clinics and day hospitals. A close relationship should exist with geriatrics, and in a few cases (especially where geriatrics and psychogeriatrics are located apart from each other) there are joint "psychogeriatric assessment units", in which psychiatrists and geriatricians collaborate. In Nottingham's Department of Health Care of the Elderly, geriatricians, psychogeriatricians and related staff have worked together in one department.

Longer-stay units, also offering respite admission, nowadays are smaller and more "domestic", and often close to their local communities. Much long-stay care is now private. Long-stay care remains the "Achilles heel" of the care of the elderly; the government's reaction to the report of its Royal Commission on Long-stay Care is still awaited[16], whilst a series of National Required Standards on all aspects of long-stay care are currently about to go out to consultation[17].

Wattis' analysis gives some support to the claim that services for older people provided by specialist psychogeriatricians are stronger than those provided by general psychiatrists who spend only a minority of their clinical time in old age psychiatry[8]. Such specialist services have significantly more consultant and non-medical staff time per thousand elderly served and are more likely to have acute beds on a district general hospital site and long-stay beds within the catchment area served. Their consultants are more likely to be involved in educational activities and to report research interests.

Voluntary Organizations

There has been a great growth of public awareness of the problems of mentally ill older people and of those who look after them. Bodies such as the Alzheimer's Disease Societies (now active in many countries) form a generally vigorous alliance with the professions as pressure groups, sources of information or support, or as fund-raisers.

Research[8]

There is nowadays hardly a relevant university department that is not concerned with the mental disorders of old age; biological research on the dementias has moved fast, as has clinical research and research on services and on carers. National and international collaboration in clinical and epidemiological studies is growing. A major longitudinal study of cognitive change in old people under the auspices of the Medical Research Council has been completed. The advent of journals such as the *International Journal of Geriatric Psychiatry* and *International Psychogeriatrics* reflects the clearer identity of the field and the growth of research activity.

Education and Entry to the Specialty[4]

Demands for teaching come from the health professions and beyond (e.g. police, clergy, architects, designers). Teaching in old age psychiatry is now common in the training of most of the health professions, and post-qualification courses are increasingly available. Day symposia abound. To enter the specialty in the UK, doctors need first to complete the 3 year basic training in psychiatry before taking the MRCPsych diploma of the Royal College of Psychiatrists, which will usually include 6 months in a psychogeriatric unit. Following the examination, higher trainees, in psychogeriatrics will spend 2 years in a psychogeriatric service and 2 years in general psychiatry, usually maintaining links with the former through clinical work or research and obtaining special experience (e.g. in geriatric medicine, neurology or management). Such training will qualify the doctor for a post as a psychogeriatrician, i.e. a psychiatrist devoting all or the bulk of his/her time to the psychiatry of old age. Higher trainees in general psychiatry may opt to spend a year in psychogeriatrics, and would then be qualified to take a "special interest" post, such as may exist in small districts. Many "doctors with domestic commitments" have trained part-time in psychogeriatrics.

Training arrangements will need to be adjusted for doctors who, having opted to do a year in psychogeriatrics, decide that they want this to become their main activity and so will wish to complete the full 2 years. In a new specialty there need to be clear standards and carefully monitored training, along with flexibility. Table 3.1 summarizes the range and scope of the work.

Table 3.1. What does a psychogeriatric service do?

Assessment
Diagnosis

Research

INTERNATIONAL DEVELOPMENTS

Psychogeriatric services are now in being in most developed countries, and there is activity in this field in the Third World too[20]. The International Psychogeriatric Association is a thriving body, as is the World Psychiatric Association's Geriatric Psychiatry Section, which has lately published a series of broadly-based Consensus Statements on the content of the specialty, on Organization and on Education[21].

The Development in the USA, 1600–1900

W. Andrew Achenbaum, Crystal Cederquist, Vicki Kahl, Kathryn Rosenberg
University of Michigan, Ann Arbor, MI, USA

There is a dearth of information about the care of mentally ill older persons in the USA from the seventeenth through the nineteenth centuries. Despite an extensive literature on the history of the various stages of the mental health movement during the period, little is known about the treatment of the aged, members of ethnic and religious minority groups, or of women of any age who became ill between 1600 and 1900. Much reported here refers to a largely white, male, New England data set. Virtually no evidence comes from the south or from west of the Mississippi.

In colonial times the mentally ill, along with other classes of dependents, were treated as a local responsibility, primarily placed with their own or other families. Clergy and physicians alike subscribed to a belief in demoniacal possession that was widespread in seventeenth century America. Few colonial doctors investigated other possible causes of mental disorders; no "scientific" theory for dealing with the mentally ill was yet in vogue.

Legal cases involving persons suffering from mental illness were decided on an individual basis. In 1639, the Massachusetts General Court was empowered to determine settlement for wandering individuals. Six years later, as a result of the need for such rulings, three men were selected to form a committee to consider provisions of a law for "disposing of inmates and settling impotent aged persons and vagrants"[1]. It is probable that a significant minority of the people affected by this law were mentally ill, but the extant records do not yield adequate documentation to verify the incidence or treatment of such cases.

The "violent" insane among public dependents were ordinarily treated as common criminals. The harmless mentally ill were treated almost the same as other paupers. Records have been found as early as 1676 of the levy of a small tax on a village in Massachusetts to help one man build and maintain a small block house for his son, who was "bereft of his natural senses"[2].

In an effort to deal with its indigent and insane citizens, Boston in the late 1600s established the first almshouse in New England. Following English custom (which was to continue in America well into the nineteenth century), indigents and petty offenders were herded indiscriminately into this poorhouse—the sick and well, the able-bodied and impotent, and law-breaking and law-abiding, young and aged, "worthy poor" and vagrants, sane and insane. In 1736, the "Poor-House, Work-House, and House of Corrections of New York City" was built in Manhattan. Elsewhere, poorhouses and houses of corrections also served as repositories for the mentally ill. The founding of the Pennsylvania Hospital in 1752 (with its special section for the insane in the basement) and in 1773 the opening of the Virginia Eastern Asylum (the first American institution exclusively for mental patients) at Williamsburg, Virginia, provided crucial steps in a more humane treatment orientation for the mentally ill. No special treatment for the elderly on account of their age, however, was instituted.

Besides attempts to effect reforms to help the insane during the Revolutionary period (*c.* 1765–1820), a few Americans challenged prevailing beliefs. Dr Benjamin Rush, who joined the staff of physicians at Pennsylvania Hospital in 1783, became known as the Father of American Psychiatry, in part because he advanced the humane and intelligent treatment of the insane. In addition to studying the effects of the moon on mental illness, Rush proposed that ill women and men engage in meaningful work, a forerunner of occupational therapy. He wanted patients to write down all that troubled their minds. Rush believed in kind treatment: asylums were to hire intelligent men and women to attend the patients. All visitors who had a disturbing effect on patients were to be excluded.

Rush's views on mental health in late life are worth mentioning, because they anticipated later views and because so few of his contemporaries took an interest in the subject. Older people, he felt, were naturally protected against certain maladies; madness, he observed, tended to attack mainly between the ages of 20 and 50. In his *Medical Inquiries and Other Observations on Diseases of the Mind*[3], Rush claimed that "the moral faculties, when properly regulated and directed, never partake of the decay of the intellectual faculties in old age, even in persons of uncultivated minds". Potential, not just decline, characterized even those past 80 years of age.

Ironically, the "enlightened" view that older persons did not suffer as greatly as younger people from the scourges of mental impairment justified, for many Americans, the view that it was acceptable to treat elderly persons who did need help as "invisible lunatics". This perception was reinforced by two trends. First, in the wake of the Revolution, a rising tide of humanitarianism dominated reformist thought in the early 1800s. Officials removed restraints in mental hospitals in the expectation that more humane treatment would facilitate recovery. This "moral treatment" concept dominated psychiatric practice for over 20 years until the 1830s, when it was abandoned. Karl Menninger[4] attributes its decline to the influx of immigrants crowding the hospitals and the emergence of a new scientific perspective. Second, physicians such as Dr Weir Mitchell and Dr Pliny Earle assembled a battery of statistics to convince the medical profession that mental illness was incurable[5,6]. If so, lifetime follow-ups would inevitably disclose recurrences of mental illness in a patient. This prognosis struck a death blow at moral treatment, and ushered in a long era of therapeutic nihilism. "Psychiatrists tended more and more," claims Gerald Grob, America's foremost scholar of the history of mental illness, "to disregard the psychogenic aspects of mental illness and to emphasize its somatic etiology"[7].

In this context, there seemed to be little sense in doing much for the old. The elderly were discouraged from care in the state psychiatric hospitals, because they were thought, by virtue of their age, to be untreatable. If there were low probability that insanity could be cured even if detected early and treated aggressively, the elderly should not be allowed to take up valuable space that could be used to treat the curable. Therefore, custodial care for the elderly insane was the best that could be provided by families, almshouses, or prisons[8,9].

The elderly, nevertheless, represented a significant proportion of the institutionalized population. A comprehensive survey of insanity among the general population of Massachusetts conducted in 1854, for instance, revealed that insane people in asylums aged 60 and above made up 9.8% of the inmates. Nearly one out of every five insane persons in Massachusetts was over 60 years old. Despite such data, Rosenkrantz and Vinovskis[10] maintain that the pervasiveness of insanity among the elderly was not recognized by nineteenth century physicians; the elderly insane remained the least likely age group to be institutionalized.

A lack of systematic record-keeping concerning mental health admissions of the aged prior to 1900 makes it hazardous to generalize about trends. Even so, based on nineteenth century data from Massachusetts, the following propositions seem warranted. On the one hand, admission rates fluctuated from one decade to the next, which suggests that those who ran institutions had considerable power to determine who could enter. On the other hand, men outnumbered women in asylums, probably because families found older women more deserving of support and less disruptive or threatening in behavior. Alcohol abuse, it is worth noting, was more likely to be cited as a diagnosis of insanity for males[8].

Because of the prevailing nihilism, the dependent elderly were generally sent to local almshouses rather than mental institutions prior to 1890[11]. Superintendents may have discouraged the admission of elderly patients, considering them a threat to the therapeutic mission of the hospital. However, records showed that patients over 70 were not troublesome and were kindly tolerated. They did receive less specific medical therapy than younger inmates. Curiously, given the rampant nihilism, what care they received apparently proved efficacious: more than half of those in institutions in their seventh decade were discharged due to recovery or improvement. The rest, however, usually stayed until death.

Because a significant proportion of mental patients aged in place, it is not surprising that the percentage of the elderly in institutions was greater than that in the general population. In 1880, there were 140 public and private mental hospitals caring for nearly 41 000 patients; 9300 were kept in almshouses; the rest were cared for in their own homes. The Census of 1880 showed 91 997 insane persons out of a total American population of 50 000 000; 52% were female, 71% native born, and 93% white. Responsibility for the aged insane was usually divided between local almshouses and mental hospitals. Between 1880 and 1890, insane persons constituted nearly a quarter of the total almshouse population. Between 1851 and 1890 nearly 10% of California's institutionalized insane were 60 years or older; in Arizona in 1900 the figure was only 1.71%; and in Massachusetts in the 1880s it was 12.1%. Most of the aged insane were said to be suffering from some form of senility.

The increasing use of the term "senility" to characterize impairments in mental health in later years signals the emergence of new scientific views of senescence. William James in *Principles of Psychology*[12] and George Beard in *American Nervousness*[13] contended that the majority of the elderly invariably experienced a decline in mental faculties and a decreased ability to learn new materials and/or to adapt to changing circumstance. Charles Brown-Séquard hypothesized that the decline resulted from "diminishing action of the spermatic glands". W. A. N. Dorland[14] believed that people's "creativity" declined after age 60. Metchnikoff's attribution of old age to a chronic disease process is indicative of the pessimistic thought regarding the well-being of the elderly in general[15]. In view of such thought, it is not surprising that the elderly mentally ill were regarded as quite hopeless and undeserving of efforts at rehabilitation. Indeed, there was so little interest in this population that "geriatrics" did not become a medical specialty until the twentieth century under the influence of Dr I. L. Nascher[16].

As basic processes of aging became a focus of scientific inquiry for a growing number of researchers, others tried to understand the etiology of more late-life disorders. Alois Alzheimer established (in a 1907 report) a histologic picture of the disease that would later bear his name. But there was not much interest in old age-associated dementia until increases in adult life expectancy started to change the demographic make-up of industrial societies[17].

In the Beginning

The Late Felix Post

In 1943, after a year's early training as one of the war-time refugees of the Maudsley Hospital, Professor Aubrey Lewis passed me on to Professor D. K. Henderson and the Royal Edinburgh Hospital for Nervous and Mental Diseases, where I initially worked in the private department. During one of his rounds, Henderson said to me: "Post, do you see all these old people here? Why don't you write 'em up?" This I obediently did, and my article appeared in the *Journal of Mental Science*[1]. The article started by demonstrating that the admission rate of patients over 60 to the Royal Edinburgh Hospital had risen between 1901 and 1941 more steeply than the proportion of this age group in the Scottish population. Interestingly, at this early date, I had found no difficulties in the differential diagnosis of my colleagues' and my own patients. There were 22 senile, arteriosclerotic and presenile dementia patients, 20 manic–depressive patients, 25 patients suffering from involutional or senile melancholia and 51 patients with schizophrenia. Assuming that the functional psychoses were the concern of general psychiatry, the rest of the paper dealt with the dementias and with an attempt to link the type associated with delusions and hallucinations to earlier personality characteristics. I noted that a high proportion of dementia admissions had been precipitated by terminal confusional states, and that of 111 patients admitted over the preceding 4 years with organic psychoses, only 23 were still occupying beds. I made the false prediction that in the future the main burden of the hospital services would be represented by the chronicity and survival of melancholic and paranoid patients. I did not anticipate that electroconvulsive therapy (ECT) and antidepressive drugs, while producing lasting recoveries in only 25% of cases, would make at least temporary discharge from inpatient care possible in most cases.

Aubrey Lewis was more farsighted. He had published, with a psychiatric social worker[3] a paper describing the psychiatric and social features of the patients in the Tooting Bec Hospital for Senile Dementia, London, UK, and in 1946 predicted, in the *Journal of Mental Science*[3] that ageing and senility would become a major problem of psychiatry.

After army service, I consulted Lewis about possible positions and he recommended me for the post of assistant physician at the Maudsley Hospital. I flattered myself that in me Lewis had seen a future brilliant psychiatrist, but was soon to be disillusioned. Even before the Bethlem Royal and Maudsley Hospitals were united in 1948, Lewis had conceived the idea of using some of the Bethlem beds to establish a unit for patients over the age of 60. After a heated discussion with the Bethlem matron, Lewis obtained agreement for the admission of senile patients to a hospital which, like the Maudsley, had previously admitted only patients thought to be recoverable. Uncovering his batteries, he asked me to take on the development of this Geriatric Unit. Once again, I obeyed (to say without enthusiasm would be an understatement) and, right up to my retirement, I continued also to run a unit and outpatient clinic for younger adults.

A report in the *Bethlem Maudsley Gazette*[4] demonstrated that both the Bethlem staff and I had "caught fire". The article started with a tribute to Professor Aubrey Lewis and his almost revolutionary idea of including experience in geriatric psychiatry within postgraduate training. The article went on to describe how patients over 60 had gradually infiltrated the Bethlem wards to emerge as a unit for 26 women and 20 men. The two wards were staffed by the same number of senior and junior nurses as the other adult wards, with two trainee psychiatrists changing every 6 months to other departments. There was one psychiatric social worker (PSW), later usually assisted by a trainee. The occupational therapy department had collaborated with the nursing staff to devise and carry out a daily occupational programme as well as socializing activities. The PSW ran a weekly afternoon of handicrafts, tea and talk near the Maudsley, where throughout my tenure I conducted a weekly follow-up and supportive clinic. The first year during which the unit had been in full swing was 1952, and it was recorded that during that year there had been 3.00 admissions to each geriatric bed compared to 3.74 admissions to each general psychiatric place. Patients who had been dementing, but whose home care was no longer possible had been excluded from admission, though not rigidly, as well as patients with recurring illnesses that had been adequately treated at the Bethlem-Maudsley or other hospitals. Of 133 patients, nine died, only four had to be transferred to their regional mental hospitals, seven were resettled in homes for the elderly, while 113 could be returned to family care. One year after discharge, information was successfully obtained about 121 of 124 cases. Seven patients had died, including one suicide of a woman who had discharged herself. Thirty ex-patients had to be readmitted to our or other hospitals, thirty-five were still outside hospital but by no means symptom-free, but 45 patients would be classified as recovered. These relatively favourable results were due to 89 patients having suffered from affective illnesses: 24 had symptoms associated with brain damage, 10 were mainly paranoid and 10 were regarded as having psychoneurosis. In spite of 4–6 weeks of conservative management 52 patients had to be given ECT. I concluded the article by pointing to research needs and by opining that with 30–40% of patients admitted to British mental hospitals being over the age of 60, training in the special problems of this age group was essential for all entrants to general psychiatry.

The history of the beginning would be incomplete without a brief account of further developments. My little textbook (rightly out of print) and publications on the long-term outcome of

affective, paraphrenic and schizo-affective illnesses were largely my own work, but many of the junior psychiatrists made contributions and they and clinical psychologists, as well as social workers, instigated their own researches. Many later made a name for themselves, and some became leading psychogeriatricians. Among them were Tom Arie, the late L. K. Hemsi, David Jolley, Robin Jacoby, David Kay, Kenneth Shulman and, last but certainly not least, Raymond Levy. After the Bethlem-Maudsley had accepted a district commitment and the admission of involuntary (sectioned) patients, Raymond Levy and my successor, Klaus Bergmann (not a Bethlem trainee), managed to move the Geriatric Unit to the Maudsley, so much closer to the patients' family homes. Raymond Levy succeeded in establishing an Academic Department of Old Age Psychiatry, which has continued to conduct research into the dementias of late life, that most important subject, previously neglected on account of admission restrictions before the hospital abandoned its ivory tower to accept a district commitment. With similar developments elsewhere, psychogeriatrics became a world movement, and Sir Aubrey Lewis would be pleased.

General Theories of Aging

Ewald W. Busse

Duke University Medical Center, Durham, NC, USA

INTRODUCTION

There is no satisfactory composite theory of aging, but numerous theories have been advanced to explain how and why living organisms age and die[1,2]. Given the multidimensionality of human beings, many theories of aging, some familiar and some overlapping, have been developed. Theories of aging are usually grouped by biological, psychological, or sociological sciences. A comprehensive review of theories of aging is beyond the scope of this chapter. However, the selected theories that are to be reviewed are particularly relevant to the psychiatry of old age.

Depending on the discipline, the phenomenon of aging takes on different definitions. Biologic aging is made up of a number of undesirable processes. There are multiple processes of aging that result in a decline in efficiency of the organism and end in its death. Aging, particularly in the psychosocial sciences, often includes a desirable process of maturation, that is, acquiring a desirable quality such as wisdom.

THE BIOLOGICAL THEORIES OF AGING

Biological theories of aging can be broken down into two broad categories: the developmental genetic theories (primary aging) and the stochastic theories (secondary aging processes)[3,4]. Primary aging refers to those declines in function that are genetically controlled, while secondary (stochastic) aging consists of random changes resulting from acquired disease and trauma. If the hostile events related to secondary aging could be prevented, life would be extended but, because of primary aging, decline and death are inevitable.

Deliberate Biological Programming

Hayflick and Moorhead[5] made an important contribution to our understanding of cellular aging. They demonstrated that human mitotic cells would divide a finite number of times and then the cell culture would die. Numerous studies demonstrated that the "normal" cells have a memory for the number of duplications, which is believed to be encoded in the genetic material. In contrast, cancer cells have abnormal chromosomes and have the capacity for dividing endlessly.

The capacity for a programmed cell death that exists in mitotic (dividing) cells is also present in postmitotic (non-dividing) cells. Cells incapable of dividing, such as neurons, do age and die. Certain types of brain cells, such as those located in the hypothalamus, appear to be much more vulnerable than others. In aging, not only are neurons lost, but there are alterations of neuronal synapses and networks[6].

Apoptosis is a "physiological normal process by which multicellular organisms get rid of injured, infected or developmentally unnecessary cells"[7,8]. Apoptosis is similar, if not identical, to a programmed cell death. The term is derived from Greek and means the dropping of petals from flowers or leaves from trees. The term "necrosis" is also commonly used to describe another kind of cell death. Necrosis is a type of cell death that is the result of the failure of nutrients to reach the cell. Death by necrosis is quite different from death by apoptosis. In necrosis the cells blow up, spill their contents and start an immune response. In apoptosis, however, the cells seem to condense, but develop blebs that separate and form "apoptosis bodies". Apoptosis bodies undergo rapid phagocytosis; thus, in apoptosis the cells die with little observable reaction, while when they die of necrosis they produce a widespread inflammatory response.

Genetics of Human Aging

In humans and in many other animal species, females outlive males and this difference can be attributed to genetic factors, as the male has a Y and an X chromosome and the female has two X chromosomes. The small Y chromosome does not appear to contain sufficient genetic material for the normal development or well-being of a human. Its primary function is to provide male characteristics[9]. Chromosomes contain the vast majority of genes, but a few exist within the mitochondria. Mitochondrial genes are important to aerobic respiration and age changes. All mitochondrial genes are inherited from the mother[10].

The Aging Clock

Miller provides a working definition of aging as follows: "Aging is a process that converts fit adults into frail adults with a progressive increased risk of illness, injury and death"[11]. He favors as an explanation for aging the existence of a single aging clock. This aging clock is in turn linked to many of the observed biological clocks that are seen in both humans and animals. Miller holds that a useful way of determining biological age will eventually emerge rather than depending upon chronological age. He supports the view that the genetic control of lifespan should be considered relatively minor. He believes that it influences lifespan at no more than 15–35%. Living in a favorable

environment and having favorable living habits influence most of the lifespan.

Inherent in our functioning are the biological rhythms observed at the hormonal levels. Many of the biological rhythms are synchronized by control centers within the brainstem. The hypothalamus plays a particularly important role in the losses of homeostatic mechanisms in the body. The responsible nuclei (clusters of cells within the hypothalamus) change with aging. These cells decline not only in number but also in efficiency. Sleep changes in late life are clearly associated with alteration of control centers within the brainstem. Van Gool and Mirmiran[12] propose that our biological rhythms become desynchronized as we age.

The Free Radical Theory

A free radical is often considered a molecular fragment, as it has an unpaired electron. It is unstable and highly reactive. Free radicals are ubiquitous in living substances and are produced by normal metabolic processes as well as by external causes such as ionizing radiation, ozone and chemical toxins. Free radicals have been linked to DNA damage, the cross-linkage of collagen and the accumulation of age pigments[13,14].

The Accumulation of Waste

With the passage of time, certain pigments such as lipofuscin accumulate in neurons and other cells. While there is no direct evidence that these pigments may be harmful to these cells, there is an association with the wear and tear of aging. Interestingly, the accumulation of lipofuscin is limited to the cells that are capable of dividing[15].

The Immune System and Aging

The autoimmune theory of aging was proposed by Burnett[16], Walford[17] and Comfort[18]. It was suggested that a small number of immunologically competent cells may mutate in such a fashion as to lose their tolerance to their host antigen and subsequently give rise to a clone of "renegade" cells[19], producing antibodies that might result in death or damage in a large number of cells, including neurons. "Anti-brain antibodies" are believed to be related to neuronal injury in senile dementia of the Alzheimer type. Autoimmunity to vascular antigens has also been reported[20].

The immune system is a complex network, but it has been found that restoring certain components can improve immunity. Interleukin-2 (IL-2) declines with age and it appears that the administration of IL-2 may retard the human aging processes[21].

Caloric Restriction and Aging

It is well established that physical inactivity and overeating contribute to obesity, which in turn increases morbidity and mortality[22]. Determining the pathophysiology of overeating is being given considerable attention. It appears that oxidative stress associated with excess caloric intake results in damage that impacts on the process of senescence and various diseases common in late life. In contrast, a calorie-restricted diet in laboratory animals results in an increase in average lifespan. However, it is unclear whether further caloric restrictions in non-obese humans will add to life expectancy.

Other Biological Theories of Aging

The disposable soma theory holds that nature's demand for reproduction takes precedence over a demand for longevity[23]. Nature gives a priority to those traits that are inherent in the organism that favor reproductive success—traits that enhance their fecundity. Hence, somatic cells are disposed of after achieving reproductive success. However, it appears that the selection of traits that are favorable for reproduction may indirectly influence lifespan because the increased reserve capacity to carry an animal to and through a longer reproductive life also adds to the animal's capacity to live longer.

The brain–body weight theory is based on evidence that the heavier the brain when compared to the weight of the body, the more likely the organism is to be inclined to longevity[24]. This relationship of brain and body is called "the index of cephalization". Naturally there are deviations from this correlation and this in turn has made the theory of limited validity.

Biophysicists have proposed a theory of aging that aims to explain why larger living organisms tend to live longer than smaller organisms. One explanation is that "lifespan tends to lengthen and metabolism slows down in proportion to the quarter power of the animal's body weight", or what might be called a "scaling theory" of aging[25]. The theory is sometimes linked to the system of distributing nutrients. The rate of a heartbeat is relevant to the distribution of nutrients. For example, the elephant lives much longer than the chicken and has a much slower heart rate. However, the capillaries of elephants are the same size as those found in the chicken.

PSYCHOLOGICAL THEORIES OF AGING

Psychologists have accumulated a wealth of information regarding mental stability and change in late life. As in biology, this information has not been integrated into a viable comprehensive theory. The main areas that have been studied by psychologists can be placed in three broad categories: cognition, personality and coping mechanisms.

Cognitive Psychology

The term "cognition" subsumes the range of human intellectual functioning[26]. Cognition is to perceive, to remember, to reason, to make decisions, to solve problems and to integrate complex knowledge. Measures of various types of cognition are influenced by chronological age, environment, task characteristics and other influences. With advancing age, individual differences in cognitive functions seem to increase. A comprehensive coverage of the studies on intelligence and memory in old age is beyond the scope of this chapter and will be presented at greater length in Section BIII, while basic concepts in those areas will be introduced in this chapter. In general, adults with high intelligence and education will show minimum decline in their performances with increasing age, while a significant decline is observed in adults with lower intelligence and age. However, older adults in general tend to perform less well in new or novel situations[26].

Loss of memory is a common complaint of old age and has received considerable attention by psychologists. There are several theoretical models of memory functioning. Such theories attempt to define various stages of information processing. Often attempts are made to distinguish short-term from long-term memory. Other theorists talk about primary, secondary and tertiary memory.

Research on intellectual functioning has been under way for many years and has been productive. Intellectual performance

seems to be strongly influenced by physical health. However, patterns of stability and change across the life cycle vary according to the ability that is being measured[26]. Perlmutter[27] crystallizes the issue of psychological change and stability by positing a ''multiprocess phenomenon conception'', as opposed to Baltes' ''dual process phenomenon conception'' of development followed by decline[28]. Perlmutter sees decline as neither inevitable nor universal and says that some cognitive skills may improve or may be acquired as one ages. However, as one reaches the point of ''terminal drop''[29], which is a curvilinear decline related to the distance of death rather than old age itself, there will be a decline in intellectual functioning.

Schaie's 30 stage theory of adult cognitive development attempts to formulate four cognitive stages in sequence. The first stage in childhood and adolescence is ''acquisitive'', which is followed by the ''achievement'' stage in young adulthood, then by the ''responsible and executive'' stage in the middle-aged individual, and finally the ''reintegrative'' stage in old age. The shift is translated essentially from ''What should I know?'' to ''How should I use what I know?'' to ''Why should I know?''

Ribot[31] advanced the ''cognitive regression hypothesis'' which hypothesized that the structures first formed are the last ones to degenerate in old age. This has not been proved to be a constant feature, depending on what components of cognition are being studied. Essentially, no adult age differences have been found in conservation, egocentrism and concept attainment[32]. However, when it comes to constructing classification, young children and the elderly tend to have a holistic perception, while older children and younger adults are more analytic[33–35]. The fact that older adults have an easier time learning dated items and retrieving dated items follows Ribot's law. In regard to free recall, older adults as well as younger children use motoric encoding and real-life objects and do not score as well as young adults, who perform better on standard memory tasks[36].

Personality Theories

Thomae and Lehr[37] have proposed an antistage theory of aging, where personality, development and adjustment are affected by the historical events throughout the life cycle. This theory is in partial conflict with the eight-stage theory of Erikson[38], which is a stage theory of ego development through the life cycle, culminating with the stage of maturity, as the elderly person may find either ego integrity through satisfaction with his past life, or despair and disgust over past failures. Bortwinick[39] has noted increasing cautiousness with advancing age, with the degree of cautiousness being influenced by the type of problem and its timing. Okun *et al.*[40] point out that cautiousness is not strictly an age effect, but that differences can be attributed to cohort influence.

According to Neugarten and Gutman[41], people maintain their personality characteristics in late life. When personality changes occur, they appear to be related to losses, particularly those involving health and social support systems. Some sex differences are noted; men are more affiliative and more nurturant, women are more individualistic and more aggressive as they become older.

Costa and McCrae[42], in their literature review on personality stability throughout the life cycle, also report that series of longitudinal studies show stability of personality traits in adulthood. The variables studied have included anxiety, introversion, conservatism, irritability or apathy. Costa and McCrae themselves have proposed five broad factors in personality traits: neuroticism, extroversion, openness to experience, agreeableness and conscientiousness. While there is stability of personality throughout the lifespan of an adult, there are generational differences, secondary to cohorts. Personality changes may be very tightly woven with mastery and the ability to cope.

SOCIAL THEORIES OF AGING

Broadly, the sociological theories of aging can be broken down into those that examine the relationship of the older person to society and those that study the role and status of the elder. In their disengagement theory, Cumming and Henry[43] claimed that the withdrawal of the elderly from their previous societal roles with reduction in all types of interaction, essentially a shift of attention from the outer world to the inner world, was desirable and helped the elderly to maintain life satisfaction. With their exchange theory of aging, Homans[44] and Blau[45] also suggested that elderly people withdrew from social interaction. Ongoing social exchanges had become more costly in old age and therefore less rewarding.

In contrast to the disengagement theory, the activity theory[46,47] proposed that activity contributes to health and life satisfaction. Undoubtedly, the selection of activities to be pursued by the elderly is limited by the decline that accompanies aging. However, remaining active is felt to be good for the elderly.

Neugarten and Gutman[41] sought a compromise in the continuity theory, by noting that older adults tend to behave in a pattern established in their earlier life as they cope and make adaptive choices. At times the person may disengage and at other times remain active. Atchley[48] felt that the continuity theory was an illusive concept because aging produces changes that cannot be completely offset, so that there is no going back to a prior state.

Age and sex stratification provide different perspectives about aging by looking at different age and sex groups with different roles and expectations. As each group moves through time, it responds to changes in the environment[49]. Riley[50] describes a cohort effect or ''cohort flow'', where a group of people born at the same time in history are together and have certain common experiences and characteristics. The status of the aged is high in static societies and tends to decline with rapid social change[51]. This ties in with Cowgill and Holmes'[52] modernization theory, which suggests that the status of the aged in any society is inversely related to the level of industrialization within that society. With industrialization, the powers and prestige of the elderly are reduced. In a primitive society aging can be a liability, but older people who continue to perform useful and valued roles have a higher standing and are well treated[52]. These sociological theories have varying degrees of validity. In sociology, as well as in biology and psychology, there are no overarching theories that incorporate the theories described above.

Structural Changes in the Aging Brain

Gandis Mazeika and P. Murali Doraiswamy
Duke University Medical Center, Durham, NC, USA

It has long been recognized that aging is associated with progressive changes in brain structure. The extent to which the brain is affected by aging is determined by a complex interplay of environmental and genetic factors. Little information is currently available on the influence of specific factors on brain aging; however, a significant amount of work has been done describing the aggregate of changes in the aging brain[1].

Methods applied to the study of brain aging have included anatomic studies and neuroimaging. Each method has specific strengths and weaknesses, leading at times to confusing and even contradictory results when comparing studies using different techniques. For instance, anatomic studies are subject to fixation artifacts and have rarely controlled for subjects' cranial size. On the other hand, magnetic resonance imaging (MRI) volumetry suffers from distortion effects due to imperfections in the magnetic field and from difficulty in precisely gauging the gray matter–white matter junction[2–4]. Furthermore, no consensus exists regarding the definition of normal brain aging. Attempts at a definition have been confounded by various problems, such as difficulties in screening out individuals with subclinical neurodegenerative disease, and difficulties in conducting adequate longitudinal studies.

Despite these shortcomings, some information is available on the regional distribution of age-associated atrophy. A general principle of brain aging that has emerged is that phylogenetically newer structures, such as neocortex and neostriatum, tend to show more age-associated atrophy than phylogenetically older structures, such as the hippocampus and brainstem.

NEUROIMAGING STUDIES

Studies using various neuroimaging techniques have repeatedly demonstrated progressive age-related volume loss in widespread areas in the brain. The overall loss of tissue volume averages 0.2%/year, starting in mid-adulthood. Changes are manifested primarily by increases in ventricular volume and by cortical atrophy, as measured by increased sulcal markings[9,10].

These changes have significant clinical consequences. Increases in ventricular volume result in decreased cerebral compliance, rendering the aging brain less resilient to changes in intracranial pressure. Cortical atrophy, on the other hand, causes the brain parenchyma to pull away from the skull table, lengthening cortical bridging veins and increasing vulnerability to subdural hemorrhages.

In neuroimaging studies, gray matter volume loss has been found to be typically greater than white matter loss. Most affected is the pre-frontal cortex, with a rate of volume loss of about 0.5%/year. Areas of moderate volume loss include the temporal, parietal and cerebellar cortex. The occipital cortex is relatively spared, while pons, tectum and hippocampus show minimal changes with normal aging[9].

Various explanations for these differences in rate of atrophy have been offered, including regional differences in calcium homeostasis and expression of inflammatory mediators, such as 5-lipoxygenase. None of these hypotheses has been verified. Another important consideration is that distortions associated with image acquisition, such as movement artifact and inhomogeneities in the magnetic field, may result in insufficient precision to accurately measure volume changes in smaller structures, such as the pons.

The relative absence of hippocampal changes in normal aging stands in contrast to the dramatic decline in hippocampal volumes observed during the course of Alzheimer's disease, frontotemporal dementia and certain other disorders, such as mesial temporal sclerosis. Some researchers have attempted to exploit this difference as a means to assist in the diagnosis of Alzheimer's disease; however, hippocampal volumetry remains an experimental technique at present[2].

Aside from changes in volume, neuroimaging has revealed other interesting structural changes with aging. The most intensely studied of these changes is the increasing prevalence of leuko-araiosis, or periventricular white matter hyperintensities. The significance of leuko-araiosis is uncertain, but is thought to be related to tissue damage as a consequence of microvascular disease. Leuko-araiosis tends to be more prominent in individuals with hypertension or diabetes, although some degree of perivascular white matter changes are found in most individuals above age 65. To date, no strong relationship has been found between leuko-araiosis and cognitive decline[3,4].

Other noteworthy age-related changes include accumulation of iron in the striatum, deep cerebellar nuclei and motor cortex and the deposition of calcium in the pineal gland, choroid plexus and in the walls of the basilar and middle cerebral arteries. The clinical significance of these changes is also uncertain.

POST-MORTEM STUDIES

One important question that cannot be addressed by neuroimaging studies is the extent of actual cell loss occurring with brain atrophy. A sizable number of gross and microanatomical post mortem studies have been conducted to investigate this and other types of anatomical changes that occur in the brain with aging, although so far very few studies have attempted to compare neuroimaging with histologic data in the same individuals[5].

Post-mortem volumetric studies have confirmed the findings from the neuroimaging literature that the frontal lobe shrinks proportionately more than the temporal, parietal and occipital lobes. In contrast to neuroimaging findings, however, is the observation that white matter volume loss appears to be greater than that found in gray matter. One possible explanation for this discrepancy is that aging seems to increase the water content of the gray matter–white matter junction, possibly distorting its apparent location on MRI imaging[5].

Post-mortem ultrastructural studies have shed light on a variety of questions regarding changes at the microscopic and cellular level. Typical findings within normal aging brains include dilated perivascular spaces (Virchow–Robin spaces), mild demyelination, reactive gliosis and appearance of vacuoles and lipofuscin within neuronal and glial cell bodies. While many of these changes are attributed to age-associated ''wear and tear'', the overall degree of white matter disorganization is mild when compared with that seen in arteriosclerotic brain disease[5–7].

An important finding confirmed in most ultrastructural studies is that most of the age-associated change in brain volume is attributable to decreases in the volumes of individual cells rather than to dropout of neurons and glia. Studies have repeatedly confirmed that the proportion of small cortical neurons increases with age. There is also some evidence for simplification of dendritic arborization with age[5].

However, evidence also exists for at least a small degree of cell loss in various regions of the brain during normal aging, including parts of the substantia nigra, the locus coeruleus and the suprachiasmatic nucleus of the hypothalamus. Some cell loss has also been demonstrated in the cortex, specifically in layers 2 and 4[6].

Other findings reported in ultrastructural studies or aging are that neurofibrillary tangles, but not amyloid plaques, appear in the CA1 cortex of the hippocampus and layer II of the entorhinal cortex. Aging also appears to affect the terminal first-order sympathetic axons, as manifested by swollen axons with neurofilamentous aggregates adjacent to the second-order sympathetic neuronal bodies[2].

SUMMARY

While there is no current consensus on the definition of normal brain aging, certain patterns have been tentatively identified. These include the observation that phylogenetically newer structures seem to atrophy at a faster rate than older structures such as the hippocampus, diencephalon and brainstem, and that most of the atrophy observed with normal aging can be attributed to cell shrinkage and dearborization, rather than to cell loss. The clinical consequences of these changes include decreased resilience to changes in intracranial pressure and increased vulnerability to subdural hemorrhages. Areas of observed significant cell loss include the substantia nigra, locus coeruleus and suprachiasmatic nucleus of the hypothalamus.

Many important unanswered questions remain regarding normal aging, including:

1. What is the relationship between structural changes in brain tissue and age-related changes in other organ systems?
2. To what extent does apoptosis affect the brain in normal aging?
3. What are the environmental and genetic determinants of the rate at which the brain ages?
4. To what extent do gender differences affect cerebral aging?
5. To what extent does cell loss in the substantia nigra, locus coeruleus and suprachiasmatic nucleus impact on the changes in balance, gait, mood and sleep pattern that are observed with aging? Is cell loss within these areas truly ''normal'' or does it represent pathology with a high degree of penetration, such as might be seen with an environmental toxin or with a ubiquitous viral infection?

Anatomy of the Aging Brain

John J. Campbell III[1] and C. Edward Coffey[1,2]

Departments of [1]Psychiatry, and [2]Neurology, Henry Ford Health System, Detroit, MI, USA

INTRODUCTION

Knowledge of the spectrum and extent of changes in brain morphology that occur with 'normal aging' is critical to any understanding of age-related illnesses, such as dementia. Prior to the recent introduction of advanced brain imaging techniques, post mortem studies served as the only source of information regarding the anatomy of the aging human brain. A common finding among them was a reduction of brain size with age, consisting initially (in the seventh decade) of atrophy of the gray matter (widening of sulci and thinning of gyri), followed by a decline in the volume of the white matter (in the eighth and ninth decades of life)[1]. The cortical atrophy appeared to be most prominent in the frontal and parietal parasagittal areas and consisted of a decrease in the volume rather than in the number of individual neurons[2]. Ventricular enlargement was also observed, but the degree of the dilatation was variable among the different studies[1,3].

There are several sources of error inherent to post mortem studies. Most of the studies included subjects with very different causes of death, which themselves can lead to a variety of changes in brain morphology; in particular, the cause of death may be quite different for young vs. elderly cohorts. Another disadvantage of the post mortem measurements is that the brain can be altered in unpredictable ways prior to tissue processing, as well as during the process of fixation[4,5].

Many of these problems have now been obviated by the development of imaging techniques, such as computed X-ray tomography (CT) and magnetic resonance imaging (MRI), which have provided an opportunity to examine the human brain *in vivo*[105]. In this chapter, we critically review those brain imaging studies that have investigated age-related changes in brain anatomy. Any understanding of these data must begin, however, with a discussion of relevant methodological issues.

ISSUES OF METHODOLOGY

Study Design

Studies of the aging brain can be classified as either cross-sectional or longitudinal. Cross-sectional studies select subjects from all age groups and examine them during roughly the same time period. Subject recruitment is relatively easy and large amounts of data can be acquired and analyzed in a short period of time. Two main limitations are inherent to cross-sectional studies; the secular or generation effect and the survivor or cohort effect. The secular effect refers to differences among successive generations with respect to variables that could influence brain anatomy. For example, differences between elderly and non-elderly cohorts with respect to nutrition or socioeconomic status could be associated with differences in brain morphology that have nothing to do with aging *per se*. The survivor effect refers to the biased selection of very healthy individuals, since those with underlying diseases usually die earlier and do not have the chance to be selected for study.

Longitudinal studies follow the same subjects with repeated examinations over time. Data acquisition is very labor-intensive and takes place over long periods of time. Longitudinal studies are limited by a period effect (changes over time in the methodology of the study) and an attrition effect (dropouts), in which the participants available at the end of the study may be quite different from the sample recruited initially.

Sample Selection

Age-related changes in brain morphology will obviously depend critically upon the criteria used to select the population under study. 'Normal' volunteers from the community may differ markedly from patients with 'clinically normal' brain CT or MRI scans with respect to variables that may influence brain anatomy. Medical and psychiatric illness, smoking, alcohol consumption, nutrition, education, environment, sex and height are just some of the variables that must be considered when comparing brain anatomy among individuals. Population heterogeneity is especially great among the elderly, and Rowe and Kahn[6] have suggested a distinction between 'usual aging' (no clinically obvious brain disease) and 'successful aging' (minimal decline in neurobiologic function in comparison with young subjects). The increased variability of measures of brain anatomy seen in 'normal' elderly populations may be due in part to the relative mix of subjects with usual vs. successful aging.

Imaging Technology

Brain imaging techniques differ in their safety, sensitivity and anatomic resolution. One of the oldest methods for *in vivo* brain imaging is pneumoencephalography (PEG). PEG is unsuitable ethically for the study of the normal brain, due to its associated discomfort and high morbidity rate. The procedure itself may also directly affect the size of the cerebrospinal fluid (CSF) spaces[7]. These problems limit the application of this technique to patients with sufficient neurologic symptomatology to warrant such an

invasive procedure. As a result, the 'normality' of the sample in studies using PEG can be easily criticized.

With advances in computer technology, two new brain imaging methods have been recently introduced, computed X-ray tomography (CT) and magnetic resonance imaging (MRI). The major advantage common to both techniques is the opportunity to study both the CSF spaces and the brain parenchyma in great detail. Computed X-ray tomography is a relatively simple and inexpensive technique, with the advantage of short study acquisition times. The method is limited, however, by low spatial and density resolution, partial volume artifacts (the effect of the coexistence of multiple tissue and fluid components in the same volume unit) and bone-hardening artifacts (false elevation of brain CT numbers adjacent to the skull)[5,8]. These technical problems have limited the ability of CT to quantitate brain changes with aging.

Magnetic resonance imaging takes advantage of the magnetic characteristics of tissue protons to study the brain. The main advantages of this technique are the excellent resolution of gray matter, white matter and CSF and the high sensitivity to disease processes, due to the fact that multiple factors (proton density, proton environment, etc.) contribute to the signal characteristics of each structure. The images are free of bone artifacts and the brain can be examined across all three major planes (i.e. axial, coronal and sagittal). Another advantage of MRI technology is that it does not utilize ionizing radiation. Disadvantages of MRI are the partial volume artifacts, the relatively longer study acquisition times and the fact that claustrophobic subjects cannot tolerate the examination due to the physical characteristics of the equipment[9,10].

Method of Image Analysis

Anatomical studies of the aging brain have used either qualitative or quantitative measures of brain morphology. In *qualitative studies*, raters employ various scales to examine the parameters of interest including, for example, the degree of cortical atrophy and ventricular enlargement. Qualitative ratings are relatively easy to use, are clinically relevant[11], do not depend on advanced instrumentation and sophisticated computations, and may display significant correlations with more quantitative methods[12]. On the other hand, the accuracy of these ratings depends on the skill of the raters and, as such, it is difficult to compare the results of studies from different authors using different scales. In addition, the sensitivity and resolution of the scales are limited by the number of rating categories (usually three to five)[13].

The *quantitative measurements* can be categorized as volumetric, planimetric (area measurement of regions of interest) or linear (distance measurement between points of interest) (Table 7.1). Volumetric methods are very accurate (according to validation studies on phantoms) and are very sensitive to changes in brain size[8,14,15]. The accuracy of the volume measurements is increased by obtaining relatively thin imaging slices (<5 mm), by reducing the interscan gap (contiguous slices are preferred) and by scanning the entire extent of the structure of interest.

Planimetric studies have the advantage of being less labor-intensive than volumetric measures and, although they correlate reasonably well with volumetric measurements, at least for structures with regular shape[12,15], their overall accuracy and sensitivity is not as good. Thus, for a simple three-dimensional structure, a doubling of the volume will result in only a 1.5-fold increase in the area of a cross-section. For more complicated shapes with irregular configurations, the correlation of planimetric to volumetric measurements is much worse.

Linear measurements are the least accurate and least sensitive, primarily because they have a non-linear relationship to volume measurements. As a result, small but potentially important changes in volume may be underestimated by linear measurements, even when used in combination[15]. Finally, it is important to note that the size of various brain structures or regions might be expected to vary with the size of the subject's brain; e.g. subjects with larger brains might be expected to have larger ventricles. Any morphometric study of brain structures across individuals should therefore take into consideration intergroup differences in brain size[15–17].

LITERATURE REVIEW

This section summarizes the effects of aging on CSF space size, size of brain parenchyma, ventricular size, and incidence of subcortical hyperintensities as reported in the literature.

Table 7.2 reviews the reported changes in the size of brain parenchyma with aging. The proportion of sulcal CSF volume to cranial volume (an indirect measure of cortical gray matter atrophy) increases from approximately 3% at the second decade of life to approximately 10% at the ninth decade. This age-related increase in sulcal CSF volume appears to accelerate after the sixth decade. Studies that have directly measured brain parenchyma have reported a 15–25% decrease in cortical gray matter volume, while the white matter, in most studies, appears to remain stable. However, studies of the corpus callosum consistently demonstrate age-related reductions in total callosal volume, particularly in the anterior regions. Finally, age-associated reductions in the areas of the pituitary and cerebellar vermis, as well as in the volume of the caudate nucleus, have been reported, though attempts at replicating those results have yielded some negative findings.

Some studies have attempted to estimate reductions in brain size indirectly by measuring changes in the volume of CSF spaces (Table 7.3). Results consistently indicate that the size of CSF spaces increases with age. More specifically, ventricular:brain ratio (VBR) may increase in a non-linear manner from 2% to

Table 7.1. Linear measurements—definitions

Bifrontal ratio Distance between the tips of the frontal horns divided by the distance between the inner tables of the skull. Measured at the slice best showing the caudate[19]

Bicaudate ratio Minimal distance between the caudate indentation of frontal horn divided by the distance between the inner tables of the skull. Measured at the slice best showing the caudate[19]

Lateral ventricular ratio Distance between the lateral walls of the bodies of the lateral ventricles divided by the distance between the inner tables of the skull. Measured at the slice showing the maximum area of bodies of lateral ventricles[16]

Cortical sulci ratio Sum of widths of the four widest sulci divided by the transpineal inner table diameter. Measured in two supraventricular slices cutting through the centrum semiovale[19]

Interhemispheric fissure ratio Maximal width of interhemispheric fissure divided by the transpineal coronal inner table diameter[19]

Sylvian fissure ratio Average of maximal Sylvian fissure width divided by the transpineal inner table diameter[19]

Third (III) ventricle ratio The product of the sagittal and coronal diameters of the IIIrd ventricle, divided by the product of the transpineal and midsagittal inner table diameters; measured at the level of maximum IIIrd ventricle area[19]

Table 7.2. Aging and changes in size of brain parenchyma

Study	Subjects	Imaging and measurement technique	Findings
Haug 1977[18]	170 Scans 0–75 years old. Subjects with 'normal neurological findings' complaining of headaches	CT, linear (maximum width of interhemispheric fissure)	Cortical atrophy increased with age; width of interhemispheric fissure increased approximately 5-fold (0.5–2.8 mm) from age 16–30 to age 61–75, in a continuous fashion
Jacoby *et al.*, 1980[19]	50 Healthy elderly volunteers, 62–88 years old, 10 M, 40 F. No history of significant psychiatric or neurologic illness. Handedness not specified	CT. Ratings (four-point scale) of cortical atrophy from films by single blinded rater; five regions rated (frontal, parietal, temporal, insular and occipital) and scores summed	Age correlated with total cortical atrophy score. Interactions with sex or laterality not reported. Adjusting for age, no relation between any CT measure and performance on the Hodkinson test of memory and orientation
Cala *et al.*, 1981[20]	115 Volunteers, 15–40 years old, 62 M, 53 F. No history of migraine, head trauma, or excessive alcohol intake (no additional details provided). All but eight subjects right-handed	CT (n = two scanners). Ratings (five-point scale) of cortical atrophy (no additional details provided). Axial slices (13 mm thick)	Age apparently associated with increased frequency of mild (grade 2) atrophy of frontal lobes and cerebellar vermis, but no statistical analysis reported. Interactions with sex or laterality not reported
Zatz *et al.*, 1982[12]	123 Normal volunteers, 20–90 years old. Unequal sex distributions among different age groups, with more women in the old group. Excluded: history of neurological problems or major medical diseases	CT. Planimetry (sulcal fluid area in two supraventricular slices divided by cranial size). Volumetric (total fluid volume in temporo-Sylvian area divided by total cranial volume). Axial slices ($n=9$) 10 mm thick, with 10 mm interscan gap; lowest slice at the level just above the petrous pyramids and orbital roofs	Increased cortical atrophy with age. Area of sulcal fluid in supraventricular levels was stable until the seventh decade then increased four-fold from age 60 to 80+ Volume of fluid in temporo-Sylvian area was stable until age 60; then increased by 30% from age 60 to age 80+
Gado *et al.*, 1983[14]	12 normal volunteers 64–81 years old. Excluded: subjects with dementia	CT. Sulcal volumetric ratio (ratio of sulcal to cranial volume). Axial slices ($n=7$), including three sections above the roof of the lateral ventricle and four below it	Increased cortical atrophy with age; cortical sulcal volume ratio increased by 13.3% in 1 year follow-up
Gomori *et al.*, 1984[21]	148 Neurologically intact patients (subjects with minor neurological symptoms and patients with lung, breast, prostate or colon cancer but no CNS involvement. All subjects had normal neurological examinations), 28–84 years old	CT. Linear (cortical sulci ratio, frontal interhemispheric fissure ratio, Sylvian fissure ratio)	Cortical atrophy increased with age; age correlated with Sylvian fissure, interhemispheric fissure and cortical sulci ratios ($r=0.53$, 0.4 and 0.2, respectively). Sylvian fissure ratio increased 1.6-fold between ages 28–49 and 80–84 continuously; interhemispheric fissure ratio increased five-fold across the same age groups continuously
Laffey *et al.*, 1984[11]	212 Normal volunteers living independently, 65 years old and older. Sex distribution same in all groups (52% M, 48% F). Excluded: alcoholism and history or findings of neurological illness	CT. Qualitative rating (five-point scale) of cortical atrophy by two experienced radiologists. Axial slice at the mid-ventricular level	Trend (not significant) for increased cortical atrophy with age; mean rating of 0.83 at age 65–69 to 1.4 at age 80–89. Males showed higher scores for cortical atrophy in all age groups
Schwartz *et al.*, 1985[5]	30 Healthy male volunteers 21–81 years old. No history of major medical, neurologic or psychiatric illness. Handedness not specified	CT. Volume measurements derived from computer-assisted segmentation technique (ASI-II program). Axial slices ($n=7$) starting from the plane of the inferior orbitomeatal line (10 mm thick, 7 mm interscan gap)	Adjusting for intracranial volume (IV), age negatively correlated with volume of gray matter and with volume of gray plus white matter, but not with white matter volume. Subjects more than 60 years old ($n=11$) had smaller volumes of thalamus, lenticular nuclei and total gray matter than younger subjects ($n=19$). Effects similar for both hemispheres
Pfefferbaum *et al.*, 1986[13]	57 Normal volunteers 20–84 years old, 27 M, 30 F	CT. Sulcal volumetric ratio (ratio of total sulcal volume to total cranial volume). Axial slices ($n=12$) with 8 mm interscan gap, starting from the level of the superior roof of the orbit and proceeding upwards	Increased cortical atrophy with age; volume ratio increased seven-fold from the third to the eighth decade. The increase was faster after age 60
Stafford *et al.*, 1988[22]	79 Normal male volunteers, 31–87 years old. Excluded: alcoholism, psychiatric illness, learning disability, severe head trauma, epilepsy, hypertension, chronic lung disease, renal disease, coronary artery disease, cancer	CT. Planimetry: ratio of cortical sulcal area to cranial area. Axial slice at supraventricular levels	Cortical atrophy increased with age; cortical sulci area ratio increased 1.8-fold between ages 30–39 and 70+ (0.012–0.022), faster after the sixth decade
Golomb *et al.*, 1993[23]	154 Healthy volunteers with MMSE > 27, 55–88 years old (70 + 8 years), 73 M, 81 F. No evidence of active medical, neurologic, or psychiatric illness. Handedness not specified	CT ($n=51$); MR imaging ($n=81$); both CT and MR imaging ($n=22$). Blinded ratings (4-point scale) of hippocampal atrophy as defined by dilatation of transverse choroidal fissure on films, by raters (n = ?) with established reliabilities	Subjects with hippocampal atrophy (rating of 2 or greater in either hemisphere; $n=50$) significantly older than those without atrophy. More males (41%) than females (25%) with hippocampal atrophy

Table 7.2 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Meyer *et al.*, 1994[24]	81 Healthy volunteers, 27–90 years old, 44 M, 37 F. No major neurologic or psychiatric illness	CT ($n=2$ scanners). Blinded measure of tissue density (densitometry) and regional brain volume (trace methodology) from axial slices (8 mm thick)	Age associated with decreased tissue density in cortical gray matter (frontal, temporal, parietal, and occipital) and in white matter (frontal only), but not in subcortical gray matter (caudate, putamen, or thalamus). Age associated with decreased ratios of cortical gray matter volume to IV and subcortical gray matter volume to IV, but not with white matter volume to IV. Interactions with sex or laterality not reported
Elwan *et al.*, 1996b[25]	88 Healthy 'lower middle class' volunteers, 40–76 years old (54.8 + 9.6 years), 57 M, 31 F. No major medical, neurologic, or psychiatric illness. All right-handed	CT. Multiple linear measurements (no additional details provided)	No correlation between age and maximal bifrontal distance, bifrontal index, maximal bicaudate distance, maximal septum–caudate distance, or cella media index. Interactions with sex or laterality not reported
Yoshii *et al.*, 1986[26]	33 Normal volunteers, 24–82 years old	Magnetic resonance (MR) imaging. Planimetry	No significant correlation between corpus callosum area and age. Trend for decline in the area of anterior half of corpus callosum with age ($r=0.31$, $p=0.8$)
Simon *et al.*, 1987[27]	48 Subjects, including normal volunteers and patients with normal MR imaging studies, 11 months to 64 years old, 25 M, 23 F. Excluded: periventricular high signal areas, anomalous development of the corpus callosum, pre-scan diagnosis of multiple sclerosis	MR imaging (0.15 tesla). Planimetry; midsagittal slice, 5 mm thick	Corpus callosum area did not change after the 18th year of age
Uematsu *et al.*, 1988[28]	17 normal male volunteers, mean age 31.5 years old, SD 5.5 years. Physically healthy	MR imaging (0.5 tesla). Planimetry; midsagittal slice 10 mm thick	No significant correlation between corpus callosum area and age
Condon *et al.*, 1988[29]	40 Volunteers, 20–60 years old, 20 M, 20 F. No additional details provided	MR imaging (0.15 tesla). Volume measurement (two raters) derived from computer-assisted pixel segmentation of contiguous sagittal slices (variable slice thickness and number)	For males but not females, age negatively correlated with ratio of total brain volume to IV. Interactions with laterality not reported
Yoshii *et al.*, 1988[30]	58 Volunteers, 21–81 years old, 29 M, 29 F. Neurologic and psychiatric histories not reported. Handedness not specified	MR imaging (1.0 tesla). Mathematically derived estimate of brain volume from inversion recovery films, based on planimetric area measurement made on single slice (10 mm thick) at level of foramen of Monro. Blinded global ratings of cortical atrophy from films (axial slices, [$n=?$], 10 mm thick, 3 mm interscan gap). Number of raters and rater reliabilities not specified	No correlation between age and brain volume. Age significantly correlated with ratings of cortical atrophy for both males and females
Hayakawa *et al.*, 1989[31]	143 Patients and seven normal volunteers, 0–60 years old. All with normal MR imaging scans	MR imaging (0.35 tesla). Planimetry; midsagittal slice 10 mm thick	Decrease in size of brain structures with age. Pituitary area decreased progressively after 20 years of age. Trend for decrease in cerebellar vermis area after the fifth decade; pontine and corpus callosum area remained stable during the adult life
Hauser *et al.*, 1989[32]	25 normal volunteers, mean age 37 years old, SD 8.6 years, 14 M, 11 F. Excluded: history of medical or psychiatric illness	MR imaging (0.5 tesla). Planimetry; midsagittal section	Corpus callosum area did not correlate with age
Jernigan *et al.*, 1990[33]	58 Healthy volunteers, 8–79 years old, 35 M, 23 F. No history of neurologic, psychiatric, or medical illness (diabetes mellitus, heart disease). Handedness not specified	MR imaging (1.5 tesla). Volume estimates (one of two raters) derived from computer-assisted pixel classification of multiple spin-echo axial images (5 mm thick, 2.5 mm interscan gap)	Age negatively correlated with ratios of cerebral volume to IV and of gray matter volume to IV. Among gray matter structures, age negatively correlated with ratios of cortical gray matter volume to IV, caudate volume to IV, and diecephalon volume to IV; but not with thalamus volume to IV or anterior cingulate volume to IV. No correlation between age and ratio of white matter volume to IV. Interactions with sex or laterality not reported

continued

Table 7.2 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Krishnan *et al.*, 1990[34]	39 Healthy volunteers, 24–79 years old, 17 M, 22 F. No evidence of major medical, neurologic, or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Stereological measurement (one of two raters) of axial slices (variable number, 5 mm thick, 2.5 mm interscan gap) from intermediate and T_2-weighted films	Age negatively correlated with total caudate volume (males = females). Caudate volume was less in subjects older than 50 years (n = 22). No adjustments for cranial size
Doraiswamy *et al.*, 1991[35]	36 Healthy volunteers (overlap with subjects Krishnan *et al.*, 1990), 26–79 years old, 16 M, 20 F. No evidence of major medical, neurologic, or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Area measurement of T_1-weighted midsagittal image using computer-assisted trace methodology. Rater reliabilities not reported	Age negatively correlated with corpus callosum area in males but not in females
Escalona *et al.*, 1991[36]	37 Healthy volunteers (overlap with subjects Krishnan *et al.*, 1990), 24–79 years old, 16 M, 21 F. No evidence of major medical, neurologic, or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Stereological measurement (one of two raters) of axial slices (variable number, 5 mm thick, 2.5 mm interscan gap) from intermediate and T_2-weighted films. Good rater reliabilities	No association between age and volume of cerebellar hemispheres
Gur *et al.*, 1991[37]	69 Healthy volunteers, 18–80 years old, 34 M, 35 F. No neurologic or psychiatric illness; 66 right-handed; three left-handed	MR imaging (1.5 tesla). Volume measurements (any two of four raters) derived from segmentation technique based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, contiguous)	Older (555 years) subjects (n = 26) had smaller whole brain volumes than younger subjects (males = females)
McDonald *et al.*, 1991[38]	36 Healthy volunteers (subjects also included in Krishnan *et al.*, 1990), 24–79 years old, 13 M, 23 F. No evidence of major medical, neurologic or psychiatric illness	MR imaging (1.5 tesla). Same as Krishnan *et al.*, 1990 (above)	Age negatively correlated with total putamen volume (males = females; left = right), but no adjustments for cranial size
Shah *et al.*, 1991[39]	36 Healthy volunteers (overlap with subjects in Krishnan *et al.*, 1990), 26–79 years old, 16 M, 20 F. No evidence of major medical, neurologic, or psychiatric illness	MR imaging (1.5 tesla). Computer-assisted measurements from T_1-weighted midsagittal films by single rater with established intra-rater reliabilities	Increasing age associated with decreasing midbrain area (males > females?). No age effects on areas of pons, medulla, anterior cerebellar vermis or 4th ventricle
Tanna *et al.*, 1991[40]	16 Healthy volunteers, 52–86 years old, 5 M, 11 F. No evidence of major medical, neurologic, or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Volume measurements (one of two raters with established reliabilities) derived from segmentation techniques based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, 2.5 mm interscan gap)	Age negatively correlated with ratio of total brain volume to total CSF plus total brain volume. Interactions with sex or laterality not reported
Coffey *et al.*, 1992[41]	76 Healthy volunteers, 36–91 years old, 25 M, 51 F. No lifetime history of neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Volume measurements (one of three blinded raters with established reliabilities) using computer-assisted trace methodology of T_1-weighted coronal images (n = 30–35, 5 mm thick, contiguous). Blinded clinical ratings (five-point scale) of 'cortical atrophy' (average score of two raters)	Age associated with decreased total volumes of the cerebral hemispheres (0.23%/year), the frontal lobes (0.55%/year), the temporal lobes (0.28%/year), and the amygdala–hippocampal complex (0.30% per year); all effects similar for males and females, and for both hemispheres. Increasing age associated with increasing odds (8.9%/year) of 'cortical atrophy', from 0.08 at age 40 to 2.82 at age 80
Doraiswamy *et al.*, 1992[42]	75 Healthy volunteers (overlap with subjects in Krishnan *et al.*, 1990), 21–82 years old (52.5 + 18 years), 34 M, 41 F. No neurologic or psychiatric illness	MR imaging (1.5 tesla). Blinded stereological measurements of volume and linear measurements of size of midbrain on T_2-weighted axial films (no additional details provided)	Age negatively correlated with midbrain volume and anteroposterior diameter, but not with red nucleus size. Effects similar for both males and females
Jack *et al.*, 1992[43]	22 Healthy elderly volunteers, 76.3 + 11.3 years old, 10 M, 12 F. No major medical or neurologic illness; no depression. Handedness not specified	MR imaging (1.5 tesla). Volume estimates (single rater) derived from computer-assisted pixel classification of T_1-weighted coronal images (4 mm thick, contiguous). Intra-rater reliabilities not reported	Age associated with decreased ratio of hippocampal volume to IV and of anterior temporal lobe volume to IV. Interactions with sex or laterality not reported
Lim *et al.*, 1992[44]	14 Healthy male volunteers, eight young (21–25 years old) and six elderly (68–76 years old). No evidence of significant medical or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Blinded volume measurements derived from semi-automated pixel segmentation of intermediate and T_2-weighted axial images (n = 8, 5 mm thick, 2.5 mm interscan gap)	Compared to younger males, older males had lower ratio of gray matter volume to IV (49.7% vs. 38.7%). No group difference in ratio of white matter volume to IV (47.2% vs. 41.2%). Interactions with laterality not reported

continues overleaf

Table 7.2 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Murphy *et al.*, 1992[45]	27 Healthy male volunteers, 19–92 years old. No major medical, neurologic or psychiatric illness. Handedness not specified	MR imaging (0.5 tesla). Blinded volume measurements using computer-assisted trace methodology of proton density axial images ($n=36$, 7 mm thick, contiguous). Manual tracing of subcortical from enhanced images. Rater reliabilities were established, but number of raters not reported	Older males (>60, $n=17$) had smaller ratios of total, left, and right hemisphere volume to IV than younger males. Older males had smaller ratios of total caudate volume to IV and of total lenticular nuclei volume to IV than younger males; no difference in ratio of total thalamus volume to IV. Reductions in caudate and lenticular volumes also found when the volumes were normalized to total brain volume, suggesting a differential effect of aging on these structures. Older males exhibited a R > L asymmetry in lenticular nuclei; the reverse was true in younger males.
Doraiswamy *et al.*, 1993[46]	Same as Doraiswamy *et al.*, 1992	MR imaging (1.5 tesla). Blinded linear measurements of interuncal distance on T_1-weighted axial image (no additional details provided)	Age associated with larger interuncal distance (NB: this measure was not correlated with amygdala volume in a follow-up study [Early *et al.*, 1993]). Interactions with sex or laterality not reported
Raz *et al.*, 1993a,b,c[47,48,49]	29 Healthy volunteers, 18–78 years old (43.8 + 21.5 years), 17 M, 12 F. No history of medical, neurologic, or psychiatric illness. All right-handed	MR imaging (0.3 tesla). Volume measurements using computer-assisted trace methodology of digitized images from the films, by two blinded raters with high reliabilities. T_1-weighted axial slices ($n=9$, 4.2 mm thick, 6.0 mm interscan gap). T_2-weighted coronal slices ($n=17$–21, 6.6 mm thick, 8.6 mm interscan gap)	After controlling for head size, age associated with decreased volumes of caudate and visual cortex (females > males). No association between age and volumes of dorsolateral prefrontal cortex, anterior cingulate gyrus, prefrontal white matter, hippocampal formation, postcentral gyrus, inferior parietal lobule or parietal white matter
Christiansen *et al.*, 1994[50]	142 healthy volunteers, 21–80 years old, 78 M, 64 F. No major medical or neurologic illness	MR imaging (1.5 tesla). Area and volume measurements using computer-assisted trace methodology of T_2-weighted axial slices ($n=15$, 4 mm thick, 4 mm interscan gap). Number of raters, their 'blindness' and their reliabilities not specified	Age associated with decreased volume of cerebral hemispheres. Interactions with sex or laterality not reported
Cowell *et al.*, 1994[51]	130 healthy volunteers (overlap with subjects in Gur *et al.*, 1991), 18–80 years old, 70 M, 60 F. No major medical, neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Volume measurements using a combination of computer-assisted trace methodology and pixel segmentation of 3D images reconstructed from T_2-weighted axial images (5 mm thick, contiguous). Good rater reliabilities, but 'blindness' not specified	Ratio of frontal lobe to IV was smaller in males over 40 years old than in younger males; no such group difference in females. In contrast, the R > L asymmetry of frontal lobe to IV was larger in older females than younger females; no such group difference in males. Ratio of temporal lobe to IV was also smaller in males over 40 years old than in younger males; no such group difference in females; no interactions with laterality. Ratio of the remaining brain volume to IV was smaller in older than younger subjects for both sexes; no interactions with laterality
DeCarli *et al.*, 1994[52]	30 Healthy male volunteers, 19–92 years old. No major medical, neurologic, or psychiatric illness. 29 Right-handed	MR imaging (0.5 tesla). Volume measurements using computer-assisted trace methodology of T_1-weighted coronal images (6 mm thick, contiguous) through temporal lobe, by single (blind?) rater	Age associated with decreased ratio of frontal lobe volume to IV but not with temporal lobe volume to IV. No interactions with laterality
Pfefferbaum *et al.*, 1994[53]	73 Healthy male volunteers (included in Pfefferbaum *et al.*, 1993), 21–70 years old (44.1 + 13.8 years). No major medical, neurologic, or psychiatric illness. Left handers included (n not specified)	MR imaging (1.5 tesla). Blinded volume measurements derived from semi-automated pixel segmentation of intermediate and T_2-weighted axial images ($n=17$–20, 5 mm thick, 2.5 mm interscan gap)	Adjusting for head size, age associated with decreased cortical gray matter volume (0.7 ml/year), but not with cortical white matter volume. Interactions with laterality not reported
Soininen *et al.*, 1994[54]	32 Healthy volunteers from the community, all with MMSE scores > 25, 16 with age-associated memory impairment (AAMI) (67.7 + 7 years; 4 M, 12 F), 16 controls (70.2 + 4.7 years; 6 M, 10 F) without AAMI. All but one right-handed	MR imaging (1.5 tesla). Blinded volume measurements using computer-assisted trace methodology of T_1-weighted coronal images (1 mm thick, contiguous) through temporal lobe, by single rater with established reliabilities	No group differences in hippocampal volumes, although controls (but not AAMI subjects) exhibited significant R > L asymmetry. No group differences in amygdala volume or asymmetry

continued

Table 7.2 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Blatter *et al.*, 1995[55]	194 Healthy volunteers, 16–65 years old, 89 M, 105 F. No history (by questionnaire) of any neurologic or psychiatric illness. 95% Right-handed	MR imaging (1.5 tesla). Volume measurements derived from semi-automated pixel segmentation and trace methodologies of intermediate and T_2-weighted axial images (5 mm thick, 2 mm gap). High rater reliabilities (blinded status?)	Adjusting for head size, age associated with decreased total brain volume and gray matter volume, but not white matter volume. Correlations tended to be higher for males than females, but these apparent differences were not analyzed. However, only females showed significant age-related reductions in gray matter. Interactions with laterality not reported
Convit *et al.*, 1995[56]	37 Healthy adult volunteers, 27 older (14 M, 13 F; 69.2 + 8.3 years old), 10 younger (5 M, 5 F; 26.1 + 4.1 years old). No evidence of stroke or major medical or psychiatric illness	MR imaging (1.5 tesla). Blinded volume measurements by single rater (reliabilities?) using computer-assisted trace methods of T_1-weighted coronal images (4 mm thick, 10% gap)	Controlling for sex and head size, age associated with volume loss in lateral temporal lobe (especially fusiform gyrus) and medial temporal lobe (especially hippocampus and parahippocampus)
Hokama *et al.*, 1995[57]	15 Healthy male community volunteers. 20–55 years old. No lifetime history of major medical, neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Volume measurements of basal ganglia using semi-automated computer assisted trace methodology from T_1-weighted coronal and axial sections (1.5 mm thick, contiguous) by raters with established reliabilities	Age associated with decreased volumes of caudate and putamen, but not of globus pallidus. No correlation between basal ganglia volumes and IQ as estimated by WAIS-R information subscale
Parashos *et al.*, 1995[58]	80 Healthy volunteers (overlap with subjects in Coffey *et al.*, 1992), 30–91 years old, 28 M, 52 F. No lifetime history of neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Blinded area measurements using computer-assisted trace methodology of T_1-weighted midsagittal image (5 mm thick), made by single rater with established rater reliabilities	Adjusting for IV, increasing age associated with smaller total and regional callosal areas, especially of anterior regions (males = females)
Fox *et al.*, 1996[59]	11 Adult volunteers with no evidence of memory impairment on testing, 5 M, 6 F; 51.3 + 5.9 years old. No additional details provided	MR imaging (1.5 tesla). Volume measurements using computer-assisted pixel segmentation of T_1-weighted coronal images (1.5 mm thick, contiguous). Scanning repeated at 12.8 + 4.3 months and volume differences determined from subtraction images	Over the follow-up period, brain volume decreased by 0.05% (~0.03 ml)
Janowsky *et al.*, 1996[60]	60 Healthy elderly volunteers, 66–94 years old (mean 78.2), 15 M, 45 F. No major medical, neurologic, or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Area measurement of corpus callosum derived from computer-assisted trace methodology. Number of raters and their 'blindness' not specified	Age associated with decreased total callosal area, anterior callosal area and middle callosal area. Interactions with sex not reported
Murphy *et al.*, 1996[61]	69 Healthy volunteers. 35 M (44 + 23 years old); 34 F (50 + 21 years old). No major medical or psychiatric illness. All right-handed	MR imaging (0.5 and 1.5 tesla). Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous coronal images (5–6 mm thick). Number of raters not specified	Relative to 'young' subjects (age 20–35 years), 'old' subjects (60–85 years) had smaller brain matter volume ratios of cerebellum to IV (males = females), cerebrum to IV (males > females), frontal lobe to IV (males > females), temporal lobe to IV (males > females), parietal lobe to IV (females > males), parieto-occipital lobe to IV (males = females), parahippocampal gyrus to IV (males = females), amygdala to IV (males = females), hippocampus to IV (females > males), thalamus to IV (males = females), lenticular nucleus to IV (males = females), and caudate to IV (males = females). For the frontal lobe, the right side decreased more than the left with age in males, but in females the left side decreased more than the right. For all other regions, there were no interactions with laterality
Deshmukh *et al.*, 1997[62]	10 Healthy male volunteers, 50.1 + 13.8 years old. No evidence of major medical, neurologic or psychiatric illness. Nine right-handed; one left-handed	MR imaging (1.5 tesla). Volume measures using semi-automated computer-assisted trace methodology from 3D T_1-weighted sagittal sections, realigned in the axial plane, by raters with established reliabilities	Age associated with decreased volume of cerebellar lobules VI–VII

continues overleaf

Table 7.2 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Jack *et al*., 1997[63]	126 Healthy elderly volunteers 51–89 years old (79.15 + 6.73 years), 44 M, 82 F. No active neurologic or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Blinded volume measurements using computer-assisted trace methodology of T_1-weighted 3D volumetric images (1.6 mm thick, contiguous, $n = 124$) by single rater with established reliabilities	Age associated with decreased volume ratio of hippocampus to IV (45.63 ml/year), amygdala to IV (20.75 ml/year), and parahippocampal gyrus to IV (46.65 ml/year); effects similar for males and females. Effects were similar for the two hemispheres, except for the parahippocampal gyrus (L > R)
Kaye *et al*., 1997[64]	30 Healthy elderly volunteers from the community, with MMSE524. All 584 years old; 14 M, 16 F. No evidence of major medical, neurologic or psychiatric illness	MR imaging (1.5 tesla). Blinded volume measurements using computer-assisted trace methodology of T_1-weighted coronal images (4 mm thick, contiguous) by raters with established reliabilities. Scanning repeated annually over a mean of 42 months	No group differences in rate of volume loss in hippocampus (about 2%/year) or parahippocampus (about 2.5%/year)
O'Brien *et al*., 1997[65]	40 Healthy community volunteers, 55–96 years old, 20 M, 20 F. No evidence of major medical or neurologic illness, or of depression or drug abuse	MR imaging (0.3 tesla). Ratings of amygdala–hippocampal atrophy from T_1-weighted coronal images (5.1 mm thick, 0.5 mm gap) by two raters with established reliabilities, blind to cognitive scores	Age associated with presence of amygdala–hippocampal atrophy
Raz *et al*., 1997[66]	148 Healthy volunteers, 18–77 years old, 66 M (47.39 + 18.07 years old); 82 F (45.72 + 6.48 years old). No major medical, neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Blinded volume measurements (digital planimetry) from scans of T_1-weighted reformatted coronal images (1.3 mm thick, contiguous). Good rater reliabilities among eight raters	Adjusted for height, age significantly related to smaller volumes of whole brain (males = females), prefrontal gray matter (males = females), inferior temporal cortex (males > females), fusiform gyrus (males = females), hippocampal formation (males = females), primary somatosensory cortex (males = females), superior parietal cortex (males = females), prefrontal white matter (males = females), and superior parietal white matter (males = females). No age effects were found for anterior cingulate cortex, parahippocampal cortex, primary motor cortex, inferior parietal cortex, visual cortex, and precentral, postcentral or inferior parietal white matter. No interactions with laterality
Salat *et al*., 1997[67]	76 Healthy elderly volunteers, 65–95 years old (mean 77.7 years), 31 M, 45 F. No major medical or neurologic illness, and no depression. All right-handed, except one left-handed F	MR imaging (1.5 tesla). Area measurements (one of three raters with established reliabilities) of corpus callosum, pons, and cerebellum using trace methodology of T_1-weighted midsagittal image	Age associated with decreased total, anterior, and middle callosum areas in females but not males. No relation of age to pons or cerebellum areas
Coffey *et al*., 1998[68]	330 Elderly volunteers living independently in the community, 66–96 years old (74.98 + 5.09), 129 M, 201 F. No history of neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla, $n = 248$; 0.35 tesla, $n = 82$). Blinded volume measurements (one of two raters with established reliabilities) using computer-assisted trace methodology of T_1-weighted axial images (5 mm thick, no interscan gap)	Adjusting for IV, age associated with decreased cerebral hemisphere volume (72.79 ml/year) (males = females), frontal region area (70.13 ml/year) (males = females), temporal–parietal region area (70.13 ml/year) (males = females), and parietal–occipital region (males > females, 70.31 vs. 70.09 ml/year, respectively). All effects similar in both hemispheres
Davatzikos and Resnik 1998[69]	114 Healthy volunteers 56–85 years old, 68 M (70.9 + 7.6 years), 46 F (69.4 + 8.0 years old). All right-handed. No additional details provided	MR imaging (1.5 tesla). Quantitative morphometry of the corpus callosum using computer-assisted trace methodology of T_1-weighted midsagittal image (1.5 mm thick). Morphometry was quantitated using a template and deformation function. No additional details provided	Age associated with decreased total and regional callosal size (males = females), with exception of anterior and posterior extremes

continued

Table 7.2 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Gunning-Dixon *et al.*, 1998[70]	Same as Raz *et al.*, 1997	MR imaging (1.5 tesla). Blinded volume measurements (digital planimetry) from scans of T_1-weighted reformatted coronal images (1.3 mm thick, contiguous). Good rater reliabilities among eight raters	Age associated with decreased caudate volume (L > R in males, R > L in females), decreased putamen volume (R > L, males = females), and decreased globus pallidus volume (males only)
Gur *et al.*, 1998[71]	17 Healthy volunteers (overlap with subjects in Gur *et al.*, 1991 and Cowell *et al.*, 1994) 31.9 + 8.9 years old, 13 M, 4 F	MR imaging (1.5 tesla). Volume measurements using a combination of computer-assisted trace methodology and pixel segmentation of 3D images reconstructed from T_2-weighted axial images (5 mm thick, contiguous). Good rater reliabilities, but 'blindness' not specified. Scanning repeated an average of 32 months later.	No significant change over follow-up period in whole brain, CSF or frontal lobe volumes. Significant volume loss was observed for L (7.5%) and R (7.2%) temporal lobes
Guttmann *et al.*, 1998[72]	72 Healthy volunteers, 18–81 years old, 22 M, 50 F. No history of psychiatric illness, epilepsy, or severe head trauma. Handedness not specified	MR imaging (1.5 tesla). Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous axial images (3 mm thick). Good interrater reliabilities	Age associated with decreased ratio of total white matter volume to IV and decreased total gray matter volume to IV. Interactions with sex or laterality not reported
Jack *et al.*, 1998[73]	24 Elderly volunteers, 70–89 years old (81.04 + 3.78 years), 8 M, 16 F. No active neurologic or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Blinded volume measurements using computer-assisted trace methodology of T_1-weighted 3D volumetric images (1.6 mm thick, contiguous, $n = 124$) by single rater with established reliabilities	Over a 12 month interval, mean hippocampal volume decreased by 1.55% and mean temporal horn volume increased by 6.15% (males = females, L = R)
Laakso *et al.*, 1998[74]	42 cognitively normal healthy elderly community volunteers, 64–79 (72 + 4) years old, 19 M, 23 F	MR imaging (1.5 tesla). Volume measures using computer-assisted trace methods from T_1-weighted coronal images (~2 mm thick, contiguous) by a single blinded rater with established reliabilities	No relation between age and hippocampal atrophy
Mueller *et al.*, 1998[75]	46 Healthy elderly volunteers 65–74 years old (6 M, 5 F), 75–84 years old (8 M, 7 F) and 85–95 years old (9 M, 11 F). All functionally independent, MMSE524, and free of major medical and neurologic illness, as well as depression. Handedness not specified	MR imaging (1.5 tesla). Volume measurements (non-blind?) using computer-assisted pixel segmentation of contiguous coronal images (4 mm thick). Excellent interrater reliabilities. Scanning repeated annually or biannually over 3–9 year follow-up	Adjusting for IV, age associated with decreased volumes of total brain, hemispheres, frontal lobes, temporal lobes, basilar–subcortical region, hippocampus, and hippocampal gyrus. Interactions with sex not reported. Over the follow-up period, significant volume decreases were seen in hippocampus (~0.02 ml/year), parahippocampal gyrus (in youngest group only, ~0.05 ml/year), parietal–occipital region (in middle and oldest age groups, ~3 ml/year), and basilar region (in middle group only, ~0.5 ml/year). No volume decreases were seen in hemispheres, frontal lobes or temporal lobes
Oguro *et al.*, 1998[76]	152 Healthy adults, 81 M, 71 F, age range 40s–70s. No evidence of neurological disease	MR imaging (0.2 tesla). Linear and area measurements using computer-assisted trace methodology from T_1-weighted midsagittal image (7 mm thick) and T_2-weighted axial images (no details), by raters ($n = ?$) with established reliabilities	Age associated with decreased linear measures of midbrain tegmentum (males only), midbrain pretectum (males and females), and base of pons (males only), but not with pontine tegmentum or fourth ventricle. Age associated with decreased area of cerebellar vermis (males only), but not of pons. Age associated with decreased ratio of cerebrum to IA (males and females) at level of third ventricle and at level of body of lateral ventricles. Interactions with laterality not reported
Pfefferbaum *et al.*, 1998[77]	28 Healthy male volunteers (overlap with Pfefferbaum *et al.*, 1994), 21–68 years old (51 + 13.8 years). No major medical, neurologic, or psychiatric illness. Left-handers included (*n* not specified)	MR imaging (1.5 tesla). Blinded volume measurements derived from semi-automated pixel segmentation of intermediate and T_2-weighted axial images ($n = 17$–20, 5 mm thick, 2.5 mm interscan gap). Scanning repeated at 5 year follow-up	Over the follow-up interval, significant decrease in total gray matter volume and in regional gray matter volume (pre-frontal gray ~2 ml, or 7%; posterior parieto-occipital gray ~1 ml, or 3.5%) (no change in frontal, anterior superior temporal, posterior superior temporal, or anterior parietal regions gray matter volume). Interactions with laterality not reported
Raz *et al.*, 1998[78]	146 Healthy volunteers (overlap with Raz *et al.*, 1997), 18–77 years old, 64 M (48 + 18 years); 82 F (46 + 17 years). No evidence of major medical, neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Blinded volume measurements (digital planimetry) from scans of T_1-weighted reformatted coronal and sagittal images (0.8 mm thick, 1.5 mm thick). Good rater reliabilities	Age associated with volume loss in cerebellar hemispheres (~2%/decade), vermis, vermian lobules VI and VII (~4%/decade), and posterior vermis (lobules VIII-X; ~2%/decade), but not in anterior vermis (lobules I–V) or pons

Table 7.3. Aging and changes in size of CSF spaces

Study	Subjects	Imaging and measurement technique	Findings
Barron *et al.*, 1976[7]	135 Volunteers, 9 months–90 years old, equal gender distribution in all age groups (8 M, 7 F per decade). No history of neurological disease; psychiatric history not reported. Handedness not specified	Computed tomography (CT). Planimetric determination of ventricular–brain ratio (VBR) by single rater (average of three measurements) from Polaroid photograph	Age associated with increased VBR and with increased variability in VBR. Interactions with sex or laterality not reported
Earnest *et al.*, 1979[79]	59 Volunteer retirees, 60–99 years old, 11 M, 48 F. Living independently and free of neurological disease. Handedness not specified	CT. Linear and planimetric measures of ventricular size at three different levels, from photographs. Linear measurements of four largest sulci. No additional data provided	Subjects 80 years or older ($n=29$) had larger ratio of ventricular size to intracranial size than did younger subjects ($n=30$). The sum of the widths of the four sulci was greater in older subjects than in younger subjects. Interactions with sex or laterality not reported
Jacoby *et al.*, 1980[19]	50 Healthy elderly volunteers, 62–88 years old, 10 M, 40 F. No history of significant psychiatric or neurologic illness. Handedness not specified	CT. Ratings (small, normal, enlarged) of ventricular size from films by single blinded rater (rater reliability not reported). Planimetric determination of ventricular–skull ratio and Evans's ratio from films by single rater (average of three measurements) with established reliabilities	8 (16%) Subjects were rated as having 'enlarged' lateral ventricles. No significant correlation between age and ventricular–skull ratio or Evans's ratio. Interactions with sex or laterality not reported. Adjusting for age, no relation between any CT measure and performance on the Hodkinson test of memory and orientation
Meese *et al.*, 1980[80]	160 Healthy 'volunteers', 1–71 years old, 10 M and 10 F in each decade. No additional data provided	CT. Linear measurements of ventricular size and sulcal width from four axial slices (no additional data provided)	Apparent age-related changes in some measures of ventricular size and sulcal width, but these changes not analyzed statistically. Interactions with sex or laterality not reported
Cala *et al.*, 1981[20]	115 Volunteers, 15–40 years old, 62 M, 53 F. No history of migraine, head trauma, or excessive alcohol intake (no additional details provided). All but eight subjects right-handed	CT. ($n=$ two scanners). Planimetric measurements of ventricular–skull ratio at level of frontal horns (no additional details provided). Axial slices (13 mm thick)	No relationship between age and ventricular–skull ratio. Interactions with sex or laterality not reported
Soininen *et al.*, 1982[81]	85 Volunteers, 53 from community and 32 from nursing home, $75+7$ years old, 23 M, 62 F. No neurological disease (no additional details provided)	CT. Linear measurements (from films?) of ventricular and sulcal size. Axial slices ($n=8$–12, 8 mm thick). No additional details provided	Age correlated with ratios of ventricular width to skull width (frontal horn index and cella media index). Age correlated with mean width of four largest sulci. Correlations were found between a composite neuro-psychological test score and the size of the lateral and IIIrd ventricles, the left Sylvian fissure, and the right temporal horn, but the effects of age were not controlled. Interactions with sex or laterality not reported
Zatz *et al.*, 1982a[12]	123 Volunteers, 10–90 years old, 49 M, 74 F. No history of neurological or major medical disease. Handedness not specified	CT. Volume measurement derived from computer-assisted pixel segmentation technique (ASI-II program). Axial slices ($n=9$, 10 mm thick, 10 mm interscan gap)	Age significantly associated with increased ventricular volume (males = females), even after controlling for intracranial volume (IV). Increased variability of ventricular size with age. Age associated with increased sulcal CSF volume, even after controlling for IV
Gado *et al.*, 1983[14]	12 Elderly volunteers, 64–81 years old, 9 M, 3 F. No additional clinical data provided	CT. Volume measurements derived from computer-assisted pixel segmentation technique (seventh axial slices, 8 mm thick). Linear measurements from axial images. Number of raters and rater reliabilities not specified	During 1 year follow-up, ratio of ventricular volume to IV increased significantly by an average of 3.7%. No significant changes in linear measures of ventricular size (VBR, IIIrd ventricular ratio, frontal horn ratio). During 1 year follow-up, ratio of sulcal volume to IV increased significantly by an average of 13%. Interactions with sex or laterality not reported
Laffey *et al.*, 1984[11]	212 Elderly volunteers, 65–89 years old, 110 M; 102 F. No evidence of alcoholism, dementia, or neurologic illness	CT. Qualitative rating (six-point scale) of ventricular enlargement and sulcal widening from films, by two experienced radiologists with established reliabilities	Age associated with increased ventricular size. No association between age and ratings of sulcal widening. Interactions with sex or laterality not reported

continued

Table 7.3 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Gomori *et al.*, 1984[21]	148 Neurologically intact volunteers, 28–84 years old. Subjects with minor neurological symptoms, patients with lung, breast, prostate, colon cancer but no CNS involvement. Neurologic exam normal	CT. Linear (sum of bicaudate and Sylvian fissure ratios)	CSF space increased with age; age correlated with the sum of the two ratios (bicaudate and Sylvian fissure, $r = 0.64$). The sum of the ratios increased two-fold between ages 28–49 and 80–89, faster after the fifth decade
Takeda *et al.*, 1984[82]	980 Patients scheduled for CT, 10–88 years old, 483 M, 497 F. Included patients with hypertension, diabetes mellitus, ischemic heart disease, lung disease and renal disease. Excluded subjects with abnormal CT	CT. Volumetric. Axial slices ($n = 7$) starting at the supraorbitomeatal line (10 mm thick, contiguous sections)	CSF space increased with age; CSF space volume displayed five-fold increase from age 40 (21.0 cm^3) to 90 (124.3 cm^3). Brain atrophy index (BAI) showed similar increase. Both CSF space volume and BAI were stable before age 40. Brain atrophy was accelerated in males during the fourth decade and the rate decreased afterwards, while atrophy in females proceeded with a stable rate throughout the lifespan. Increased variability with age
Schwartz *et al.*, 1985[5]	30 Healthy male volunteers, 21–81 years old. No history of major medical, neurologic, or psychiatric illness. Handedness not specified	CT. Volume measurements derived from computer-assisted pixel segmentation technique (ASI-II program). Axial slices ($n = 7$) starting from the plane of the inferior orbito-meatal line (10 mm thick, 7 mm interscan gap)	Age correlated with areas and volumes of lateral and IIIrd ventricles, even after adjusting for height and intracranial area. Age correlated with VBR. Increased variability of ventricular size with age. No laterality effects. Age correlated with CSF volume (ventricular plus basal cisterns), even after controlling for IV. Increased variability of CSF volume with age
Pfefferbaum *et al.*, 1986[13]	57 Healthy volunteers, 20–84 years old, 27 M, 30 F. No additional data provided	CT. Volume measurements derived from computer-assisted pixel segmentation technique (modification of Gado *et al.*, 1983). Contiguous axial slices ($n = 5$), starting at the level of the superior roof of the orbits	Age associated with increased ratio of ventricular volume to IV. Increased variability in ventricular volume with age. Interactions with sex or laterality not reported. Age associated with increased ratio of sulcal CSF volume to IV (from single axial slice [8 mm thick] approximately 48 mm from the level of the superior roof of the orbits). Age associated with increased variability of sulcal CSF volume to IV
Nagata, *et al.*, 1987[83]	500 Patients with head CT, 10–90 years old. Excluded: subjects with abnormal CT	CT. Volumetric. Axial slices ($n = 6$), beginning at the level of the basal cistern (10 mm thick)	CSF space increased with age; four-fold increase in BAI between ages 50 (2.3%) and 80 (10%). BAI was stable before the sixth decade. Increased variability with age
Stafford *et al.*, 1988[22]	79 Healthy male volunteers, 31–87 years old. No severe medical or psychiatric illness. Handedness not specified	CT. Volume measurements derived from computer-assisted pixel segmentation technique (ASI-II program). Axial slices ($n = 3$) at mid-, high- and supraventricular levels	Age associated with increased ratio of ventricular–brain volume. Age associated with increased ratio of supraventricular CSF–brain volume. Interactions with laterality not reported. Inverse correlation observed between a discriminant function of ventricular volume measures and a discriminant function of neuropsychological tests of naming and abstraction
Pearlson *et al.*, 1989[84]	31 Healthy elderly volunteers, 68.3 + 1.2 years old, 15 M, 16 F. No major medical, neurologic, or psychiatric illness. Handedness not specified	CT. Planimetric determination of VBR from films by one of two raters, each with established reliabilities	Age correlated with VBR. Interactions with sex or laterality not reported
Kaye *et al.*, 1992[85]	107 Healthy volunteers, 64 M (21–90 years old); 43 F (23–88 years old). No major medical, neurologic, or psychiatric illness. Handedness not specified	CT. Volume measurements derived from computer-assisted pixel segmentation technique (ASI-II program). Axial slices (10 mm thick, 7 mm interscan gap)	Age associated with increased ventricular volume in both males and females (about 20% per decade); precipitous increases observed beginning in the fifth decade in males and in the sixth decade in females. Interactions with laterality not reported

continues overleaf

Table 7.3. *continued*

Study	Subjects	Imaging and measurement technique	Findings
Sullivan *et al.*, 1993[86]	114 Healthy volunteers, 21–82 years old (51.2 + 17.7 years), 84 M, 30 F. No history of major medical, neurologic, or psychiatric illness. 90% Right-handed	CT. Volume measurements derived from computer-assisted pixel segmentation technique (modification of Gado *et al.*, 1983). Axial slices ($n = 10$, 10 mm thick). 10 neuropsychological tests (MMSE, Trail Making Test A and B, WAIS-R subtests—Information, Digit Span, Vocabulary, Digit Symbol, Picture Completion, Block Design, and Object Assembly)	Age correlated with total and third ventricular volume, even after adjustments for head size (males = females). No correlation between age related changes in total or third ventricular volume and performance on 10 neuropsychological tests. Age correlated with increased CSF volume in Sylvian fissure and in vertex, frontal and parieto-occipital sulci (males = females).
Shear *et al.*, 1995[87]	35 Healthy volunteers (included in Sullivan *et al.*, 1993), 67.4 + 7.4 years old, 23 M, 12 F. No history of major medical, neurologic, or psychiatric illness	CT. Longitudinal within-subject follow-up, using blinded volume measurements per technique of Sullivan *et al.*, 1993. High rater reliabilities	Over mean (+ SD) follow-up of 2.6 (+ 0.96) years, increases were observed in CSF volumes of frontal sulci (0.31 ml/year), Sylvian fissure (0.58 ml/year), parieto-occipital sulci (0.05 ml/year), and ventricular system (0.61 ml/year). Interactions with sex not reported
Elwan *et al.*, 1996[88]	88 Healthy 'lower middle class' volunteers, 40–76 years old (54.8 + 9.6 years), 57 M, 31 F. No major medical, neurologic, or psychiatric illness. All right-handed	CT. Multiple distance measurements (no additional details provided)	Age correlated with maximum width of IIIrd ventricle. Interactions with sex or laterality not reported
Grant *et al.*, 1987[89]	64 Healthy volunteers, 18–64 years old, 25 M, 39 F. No history of neurological disease; psychiatric history not reported. Handedness not specified	Magnetic resonance (MR) imaging (0.15 tesla). Mathematically derived estimate of ventricular volume and CSF volume from signal intensity measurements made on single sagittal slice (number of raters not specified)	Age associated with increased ventricular volume in males, but not females; however, this apparent gender difference was not tested statistically. Interactions with laterality not reported. Age associated with increased total (ventricular plus cisternal) cranial CSF volume (males = females). No control for size of brain or head
Condon *et al.*, 1988[29]	40 Volunteers, 20–60 years old, 20 M, 20 F. No additional details provided	MR imaging (0.15 tesla). Volume measurement (two raters) derived from computer-assisted pixel segmentation of contiguous sagittal slices (variable slice thickness and number)	For males but not females, age correlated with ratio of total ventricular volume to IV, total CSF volume to IV, and total sulcal CSF volume to IV
Yoshii *et al.*, 1988[30]	58 Healthy volunteers, 21–81 years old, 29 M, 29 F. Neurologic and psychiatric histories not reported. Handedness not specified	MR imaging (1.0 tesla). Blinded global ratings (four-point scale) of lateral ventricular enlargement from inversion recovery films (axial slices, *n* unspecified, 10 mm thick, 3 mm interscan gap). Numbers of raters and rater reliabilities not specified	Age correlated with ratings of lateral ventricular enlargement (males = females). Interactions with laterality not reported
Jernigan *et al.*, 1990[33]	58 Healthy volunteers, 8–79 years old, 35 M, 23 F. No neurologic, psychiatric, or medical (e.g. diabetes mellitus and heart disease) illness. Handedness not specified	MR imaging (1.5 tesla). Volume estimates (one of two raters) derived from computer-assisted pixel classification of multiple spin-echo axial images (5 mm thick, 2.5 mm interscan gap)	Age associated with increased ratio of ventricular CSF volume to IV. Age associated with increased ratio of sulcal CSF volume to IV. Interactions with sex or laterality not reported
Wahlund *et al.*, 1990[90]	24 Healthy elderly volunteers, 75–85 years old (mean = 79 years), 8 M, 16 F. No evidence of neurologic or psychiatric illness. Handedness not specified	MR imaging (0.02 tesla). Visual ratings (5-point scale) of CSF spaces on T_2-weighted axial films (slice = 10 mm thick, no gap) by 2 raters (blind?) with established reliabilities. Area measurements based upon computer-assisted pixel classification technique, from single axial section at level of basal ganglia	No correlation between age and visual ratings or area measurements of sulcal CSF or lateral ventricle CSF size
Gur *et al.*, 1991[37]	69 Healthy volunteers, 18–80 years old, 34 M, 35 F. No neurologic or psychiatric illness. 66 Right-handed; three left-handed	MR imaging (1.5 tesla). Volume measurements (any two of four raters) derived from segmentation technique based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, contiguous)	Older (555 years) subjects ($n = 26$) had larger total CSF volume (males > females), larger ratio of ventricular CSF volume to IV (males = females), and larger ratio of sulcal CSF volume to IV (males > females). Effects of age on ratio of ventricular CSF volume to IV were asymmetric (L > R) in males but not in females

continued

Table 7.3 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Tanna *et al.*, 1991[40]	16 Healthy volunteers, 52–86 years old, 5 M, 11 F. No evidence of major medical, neurologic or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Volume measurements (one of two raters with established reliabilities) derived from segmentation techniques based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, 2.5 mm interscan gap)	Age significantly correlated with ratio of ventricular CSF volume to total CSF plus total brain volume. Trend (non-significant) for age to be associated with increasing ratio of sulcal CSF volume to total CSF plus total brain volume. Interactions with sex or laterality not reported
Coffey *et al.*, 1992[41]	76 Healthy volunteers, 36–91 years old, 25 M, 51 F. No lifetime evidence of neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla). Volume measurements (one of three blinded raters with established reliabilities) using computer-assisted trace methodology of T_1-weighted coronal images ($n = 30$–35, 5 mm thick, contiguous). Blinded clinical ratings (five-point scale) of lateral ventricular enlargement from films (average score of two experienced raters)	Adjusting for IV, age associated with increased volumes of the third (2.8%/year) and lateral (3.2%/year) ventricles (males = females). Age associated with increased odds (7.7%/year) of at least mild lateral ventricular enlargement, from 0.10 at age 40 to 2.22 at age 80 (males = females). No interactions with laterality
Lim *et al.*, 1992[44]	14 Healthy male volunteers, 8 young (21–25 years old), 6 elderly (68–76 years old). No evidence of significant medical or psychiatric illness. Handedness not specified	MR imaging (1.5 tesla). Blinded volume measurements derived from semi-automated pixel segmentation of intermediate and T_2-weighted axial imaging ($n = 8$, 5 mm thick, 2.5 mm interscan gap)	Compared with younger males, older males had higher percentage of CSF volume to IV (8% vs. 20.1%)
Matsubayashi *et al.*, 1992[91]	73 Healthy volunteers, 59–83 years old, 24 M, 49 F. No history of major medical, neurologic, or psychiatric illness	MR imaging (0.5 tesla). Planimetric determination of ventricular–parenchymal ratio (VPR). No additional details provided	Age correlated with VPR. Interactions with sex or laterality not reported
Murphy *et al.*, 1992[45]	27 Healthy males, 19–92 years old. No major medical, neurologic, or psychiatric illness. Handedness not specified	MR imaging (0.5 tesla). Blinded volume measurements derived from semi-automated pixel segmentation of proton density axial images ($n = 36$, 7 mm thick, contiguous). Rater reliabilities established, but number of raters not specified	Compared with younger males (under 60 years old; $n = 10$), older males ($n = 17$) had larger ratios of lateral ventricular volume to IV, larger ratio of third ventricular volume to IV, and larger ratios of peripheral CSF volume (total CSF volume minus ventricular volumes) to IV. No interactions with laterality
Raz *et al.*, 1993a[47]	29 Healthy volunteers, 18–78 years old, 17 M, 12 F. No major medical, neurologic, or psychiatric illness. Self-reported right-handers	MR imaging (0.30 tesla). Blinded volume measurements from films using digital planimetry of T_1-weighted and proton density sagittal and coronal images. Good rater ($n = 2$) reliabilities	Controlling for head size, age associated with increased lateral ventricular volume (males = females). Interactions with laterality not reported
Christiansen *et al.*, 1994[50]	142 Healthy volunteers, 21–80 years old, 78 M, 64 F. No major medical or neurologic illness	MR imaging (1.5 tesla). Volume measurements using manual tracing of T_2-weighted axial images (4 mm thick, 4 mm interscan gap). No additional details provided	Age associated with increased lateral ventricle volume in males (134%) and females (66%), but these apparent gender differences were not statistically compared. Interactions with laterality not reported
DeCarli *et al.*, 1994[52]	30 Healthy male volunteers, 18–92 years old. No major medical, neurologic, or psychiatric illness. 29 Right-handed	MR imaging (0.5 tesla). Volume measurements of T_1-weighted coronal images (6 mm thick, contiguous) by single rater using computer-assisted pixel segmentation techniques. Good rater reliabilities	Age associated with increased volume of sulcal CSF to IV (1.3%/decade), central CSF to IV (0.3%/decade), and third ventricle CSF to IV (0.04%/decade). For all measures, no interactions with laterality
Pfefferbaum *et al.*, 1994[53]	73 Healthy male volunteers (included in Pfefferbaum *et al.*, 1993), 21–70 years old (44.1 + 13.8 years). No major medical, neurologic, or psychiatric illness. Left-handers included (n not specified)	MR imaging (1.5 tesla). Blinded volume measurements of T_2-weighted axial slices (5 mm thick, 2.5 mm interscan gap) by four raters using computer-assisted pixel segmentation techniques. Good rater reliabilities	Age associated with increased cortical CSF volume to IV (0.6 ml/year) and ventricular volume to IV (0.3 ml/year). Interactions with laterality not reported
Blatter *et al.*, 1995[55]	194 Healthy volunteers, 16–65 years old, 89 M, 105 F. No history (by questionnaire) of any neurologic or psychiatric illness. 95% Right-handed	MR imaging (1.5 tesla). Volume measurements derived from semi-automated pixel segmentation and trace methodologies, of intermediate and T_2-weighted axial images (5 mm thick, 2 mm gap). High rater reliabilities (blinded status?)	Adjusting for IV, age associated with increased subarachnoid CSF volume, and lateral and IIIrd ventricular volumes, but not IVth ventricular volume; correlations tended to be higher for males than females, but these apparent differences were not analyzed. Interactions with laterality not reported

continues overleaf

Table 7.3 *continued*

Study	Subjects	Imaging and measurement technique	Findings
Murphy *et al.*, 1996[61]	69 Healthy volunteers, 35 males (mean + SD age = 44 + 23 years); 34 females (mean + SD age = 50 + 21 years). No major medical or psychiatric illness. All right-handed	MR imaging (0.5 and 1.5 tesla). Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous coronal images (5–6 mm thick). Number of raters not specified	Relative to younger subjects (age 20–35 years), older subjects (60–85 years) had larger ratios of lateral ventricular volume to IV (males = females), third ventricular volume to IV (females > males), and peripheral CSF volume to IV (males = females). No interactions with laterality
Salonen *et al.*, 1997[92]	61 Healthy volunteers, 30–86 years old, 30 M, 31 F. No neurological symptoms or disease; psychiatric history not specified. Handedness not specified	MR imaging (1.0 tesla). Qualitative ratings (five-point scale) of sulcal and lateral ventricular enlargement. Linear measurement of maximum width of third ventricle. T_1-weighted axial slices (5 mm thick, 1 mm interscan gap). Number of raters and rater reliabilities not specified	Age associated with increased ratings of sulcal widening and lateral ventricular enlargement, and with width of IIIrd ventricle. Interactions with sex or laterality not reported
Yue *et al.*, 1997[93]	1488 Healthy elderly volunteers from the Cardiovascular Health Study, 65–80 + years old, numbers of males and females not specified. Handedness not specified. No major medical or neurologic illness (psychiatric illness not assessed)	MR imaging (0.35 or 1.5 tesla). Blinded ratings of sulcal prominence (10-point scale) and ventricular size (10-point scale) from T_1-weighted axial images. Good to excellent rater reliabilities, but number of raters not specified	Age associated with increased sulcal prominence and ventricular enlargement (males = females)
Coffey *et al.*, 1998[68]	330 Elderly volunteers living independently in the community, 66–96 years old (74.98 + 5.09), 129 M, 201 F. No history of neurologic or psychiatric illness. All right-handed	MR imaging (1.5 tesla, $n = 248$; 0.35 tesla, $n = 82$). Blinded volume measurements (one of two raters with established reliabilities) using computer-assisted trace methodology of T_1-weighted axial images (5 mm thick, no interscan gap)	Adjusting for IV, age associated with increased peripheral (sulcal) CSF volume, lateral fissure CSF volume, lateral ventricular volume (0.95 ml/year), and IIIrd ventricular volume (0.05 ml/year). Males showed greater age-related changes than females for peripheral CSF (2.11 ml/year vs. 0.06 ml/year, respectively) and lateral fissure volumes (0.23 ml/year vs. 0.10 ml/year, respectively). No interactions with laterality
Guttmann *et al.*, 1998[72]	72 Healthy volunteers, 18–81 years old, 22 M, 50 F. No history of psychiatric illness, epilepsy, or severe head trauma. Handedness not specified	MR imaging (1.5 tesla). Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous axial images (3 mm thick). Good interrater reliabilities	Age associated with increased ratio of total CSF volume to IV. Interactions with sex or laterality not reported
Mueller *et al.*, 1998[75]	46 Healthy elderly volunteers. 65–74 years old (6 M, 5 F), 75–84 years old (8 M, 7 F), and 85–95 years old (9 M, 11 F). All functionally independent, MMSE524, and free of major medical and neurologic illness, as well as depression. Handedness not specified	MR imaging (1.5 tesla). Volume measurements (non-blind?) using computer-assisted pixel segmentation of contiguous coronal images (4 mm thick). Excellent interrater reliabilities. Scanning repeated annually or biannually over 3–9 year follow-up	Adjusting for IV, age associated with increased temporal horn volume, but not with total CSF, sulcal CSF, or lateral ventricle volumes. Interactions with sex not reported. Over the follow-up period, significant increases were seen only in total CSF volume (~ 1.5 ml/year, females > males) and in lateral ventricular volume (~ 1.4 ml/year) (males = females)
Pfefferbaum *et al.*, 1998[77]	28 Healthy male volunteers (overlap with Pfefferbaum *et al.*, 1994) 21–68 years old (51 + 13.8 years). No major medical, neurologic, or psychiatric illness. Left-handers included (*n* not specified)	MR imaging (1.5 tesla). Blinded volume measurements derived from semi-automated pixel segmentation of intermediate and T_2-weighted axial images ($n = 17$–20, 5 mm thick, 2.5 mm interscan gap). Scanning repeated at 5 year follow-up	Over the follow-up interval, significant increase in volume of lateral (~ 5 ml, or 20%) and third ventricles, but not of cortical sulcal CSF volume

17% over the first nine decades of life. Studies using linear measurements show a two-fold enlargement while volumetric studies report a four- to five-fold volume increase. The changes in the size of CSF spaces are accelerated after midlife (60 years). The variance in measures of CSF spaces also increases with age.

The majority of the studies report a progressive enlargement of the lateral and third ventricles with age, which ranges from less than one to three times their initial sizes. No relationship has been found thus far between aging and fourth ventriclar size. As expected, studies using linear measurements show the smallest changes, while studies using planimetric and volumetric measurements agree in finding relatively greater enlargement. The increase in ventricular size is relatively minimal until the sixth decade, after which it becomes more pronounced. Finally, the variability of the measurements of ventricular size increases with age.

Table 7.4. Aging and incidence of subcortical hyperintensities (SH)

Study	Subjects	Imaging and measurement technique	Findings
George *et al*., 1986[94]	47 Normal volunteers; two age groups: < 45 years ($n = 35$) and 46–78 years ($n = 12$)	MR imaging (0.3 tesla). Qualitative rating (5-point scale) of subcortical hyperintensities (white and gray matter). Axial slices ($n = 7$) 8 mm thick with 1.2 cm interscan gap	Subcortical hyperintensities increased with age; no subject under 45 had foci of increased signal; 8/12 subjects over 46 showed single or multiple foci of increased signal
Fazekas, 1989[95]	87 Normal volunteers, 31–83 years old, 40 M, 27 F. Excluded patients with cardiovascular or cerebrovascular disease, hypertension, hyperglycemia, and neurologic or psychiatric illness	MRI (1.5 tesla). Qualitative rating (four-point scale) of subcortical hyperintensities. Axial slices ($n = 7$) intermediate and T_2-weighted, 5–8 mm thick	The incidence and severity of subcortical hyperintensities increased with age and in the presence of risk factors for vascular disease
Hendrie *et al*., 1989[96]	27 normal volunteers, 63–86 years old, 10 M, 17 F	MRI (1.5 tesla). Consensus rating (four-point scale) by two blinded raters; axial slices (T_2-weighted) 10 mm thick	Of the population 56.7% had SH; mean age increased with severity of SH
Jernigan *et al*., 1991[33]	58 Normal volunteers, 8–79 years of age, 35 M, 23 F. Excluded: diabetes mellitus, heart disease, substance abuse, developmental intellectual abnormality, psychiatric illness	MRI (1.5 tesla). Volumetric (ratio of volume of white and grey matter subcortical hyperintensities divided by cranial volume, as derived from computer-assisted pixel classification system). Axial slices of entire brain with thickness 5 mm and interscan gap 2.5 mm	SH volume ratio increased curvilinearly with age (especially after 55 years of age) from slightly over 0% at age 55 to 25% of the supratentorial volume at age 80. Increased variability with age
Matsubayashi *et al*., 1992[91]	73 Healthy volunteers, 59–83 years of age, 24 M, 49 F. No major medical, neurological or psychiatric illness	MRI (0.5 tesla). Rating (four-point scale) of periventricular SH on T_2-weighted axial slices (no additional details reported)	Subjects with highest SH rating ($n = 19$) significantly older than other groups
Boone *et al*., 1992[97]	100 Healthy volunteers, 45–83 years of age, 36 M, 64 F. No major medical, neurological or psychiatric illness	MRI (1.5 tesla). Computer-assisted area measurements of SH from T_2-weighted axial sections by single rater (additional rater information not reported)	Age greater in those subjects with the largest lesion areas
Almkvist *et al*., 1992[98]	23 Healthy volunteers, 75 years of age and older, 9 M, 14 F. No major medical, neurological, or psychiatric illness	MRI (0.02 tesla). Area measurements of SH from T_2-weighted axial sections by single blinded rater (reliabilities not reported)	No correlation between age and SH area
Coffey *et al*., 1992[41]	76 Healthy volunteers, 36–91 years old, 25 M, 51 F. No history of neurological or psychiatric illness. All right-handed	MRI (1.5 tesla). Consensus ratings of SH from intermediate and T_2-weighted axial films (four-point scale) by two blinded raters with established reliabilities	Increasing age associated with increased odds of SH in the deep white matter (6.3%/year) and pons (8.1%/year)

Table 7.4 summarizes the effects of aging on the incidence on MRI of foci of T2-signal hyperintensity in the subcortical white matter and gray matter nuclei (‘subcortical hyperintensities’). While the studies are difficult to compare because of differences in the definition/rating of subcortical hyperintensity, it is clear that the changes increase with age as well as in the presence of risk factors for vascular disease (e.g. smoking, hypertension, diabetes mellitus, coronary/peripheral vascular disease). In our study of 75 healthy adults[41], subcortical hyperintensity was present in the deep white matter in 64.0% of subjects, in the periventricular white matter in 12.0%, in the basal ganglia in 12% and in the pons in 21.3%. The odds of having subcortical hyperintensity increased from 5% to 9% per year, depending on the anatomic region involved.

QUANTITATIVE MRI AT THE HENRY FORD AGING PROGRAM

One specific aim of our Neuropsychiatry Program at Duke University Medical Center has been to examine brain structure and function in normal aging and in patients with various psychiatric illnesses, particularly affective disorders[41,99–102]. All participants are strongly right-handed and each receives an extensive medical and neuropsychiatric history interview and examination. The normal subjects have no history or clinical evidence of any psychiatric disorder or any illness referable to the brain. The majority of these ‘normal’ subjects are also free of medical illness, so that our cohort is felt to reflect primarily ‘successful’ rather than ‘usual’ aging[38].

The MRI scans of the brain are performed on high-field strength (1.5 tesla) systems. Spin-echo pulse sequences are used to produce T1-weighted ($TR = 500$ ms, $TE = 20$ ms), intermediate ($TR = 2500$ ms, $TE = 40$ ms) and T2-weighted ($TR = 2500$ ms, $TE = 80$ ms) brain images. Slices are interleaved, relatively thin (1–5 mm) and cover the entire extent of the brain in all imaging planes. Structures of interest are outlined using computer-assisted edge detection and trace methodology (Figure 7.1). The area (cm^2) within the outline is calculated automatically and volume (ml) can be determined by multiplying the area by the slice thickness and summing over the multiple slices in which the structure appears[29,38].

The intermediate and T2-weighted MRI images are obtained because they are more sensitive to some forms of pathologic tissue than the T1-weighted scans and because they permit an assessment of subcortical hyperintensities. Both the intermediate and T2-weighted scans are acquired in the axial plane of orientation. The hard copies of these scans are coded and randomized, intermixed with scans from other patient populations, and then formally rated for subcortical hyperintensities[26] by

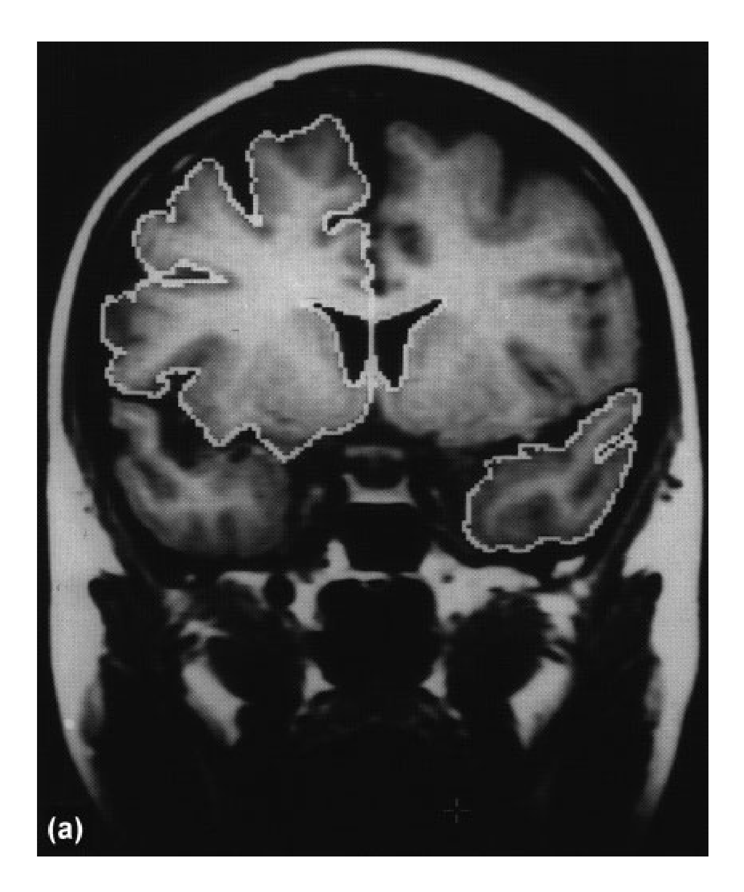

Figure 7.1 Typical coronal MRI images (TR = 500 ms, TE = 25 ms) illustrating anatomic landmarks and computer-assisted measurement of regional brain areas (A) Coronal section at level of optic chiasm, illustrating measurement of the right frontal lobe, the lateral ventricles and the left temporal lobe. (B) Coronal section at the level of the interpeduncular cistern, illustrating measurement of the left temporal lobe, the third ventricle and the right amygdala–hippocampal complex

an experienced research team that is blind to the subject's age and group status (i.e. normal control vs. patient).

These studies are ongoing, and several important findings have emerged[41,99–104]. First, our quantitative imaging and measurement techniques provide highly accurate and reliable assessments of brain size. For example, intraclass correlation coefficients for interrater reliability range from 0.88 to 0.99, depending upon the particular brain region under study. The intraclass correlation coefficients for intrarater reliability range from 0.93 to 0.99. Second, regional brain volume clearly changes with age, with a predilection for the frontal lobes. We have observed a rate of decline of about 0.23%/year for cerebral hemisphere volume. Yet the rate of decrease we have observed for the frontal lobes is twice as great (0.55%/year). Our data also indicate that age related changes in regional cerebral volume is greater for ventricular regions than for parenchymal regions (3%/year vs. 0.23–0.55%/year). Thus, ventricular enlargement may prove to be a more sensitive index of brain aging than cortical atrophy. Third, formal assessments of cortical atrophy and ventricular enlargement suggest that the statistically significant age-related changes in brain volume may not be clinically significant. That is to say, anything more than mild cortical atrophy or mild ventricular enlargement appears to be distinctly uncommon in a medically healthy sample of elderly community volunteers. Fourth, the incidence of subcortical hyperintensity increases with age, but again it is uncommon for such changes to be severe[39,96]. Fifth, the relationship between aging and changes in brain size is not a simple one, in that it may be affected by a number of covariates (e.g. sex, height, years of education) that can modify the main effects of aging[38]. For instance, we recently found that age-related changes in brain size were significantly greater in men than women for peripheral (sulcal) CSF volume, the lateral (Sylvian) fissure CSF volume, and the parieto-occipital region area[103]. In addition we have observed significant effects of years of formal education on peripheral CSF volume, a marker of cortical atrophy[104]. In a sample of healthy elderly volunteers living independently in the community and Mini Mental State Examination (MMSE) scores of at least 24, each year of education was associated with an increase in peripheral CSF volume of 1.77 ml. These findings are consistent with the 'reserve hypothesis', which posits that education (or factors for which it is a surrogate) provides a protective buffer against the injurious effects of age-related brain changes.

SUMMARY

Advanced brain imaging techniques produce highly accurate anatomic information and provide exciting opportunities to examine *in vivo* the effects of aging on the human brain. Our review of the existing literature indicates that normal aging is associated with cortical and subcortical atrophy, enlargement of the lateral and third ventricles, and an increase in subcortical hyperintensities. The extent of these anatomic changes can now be

quantitated with computer-assisted techniques and predictions can be made regarding the amount of change in tissue structure with advancing age. An important goal of future research will be to relate these anatomic changes to functional, neuropsychological and brain metabolic changes that accompany normal aging and age-related diseases of the brain.

Quantitative Structural Changes in the Ageing Brain

Bente Pakkenberg, Lisbeth Regeur, Hans Jørgen G. Gundersen*

Neurological Research Laboratory, Kommunehospitalet, Copenhagen, and
**Stereological Research Laboratory, Århus University, Århus, Denmark*

Estimates of the total number of human neocortical cells in both hemispheres range from 10 to 100 billions (10^9), but only two major studies describe how to estimate total neuron number. Reduction in the number of cells per unit volume of human cerebral cortex with age has been found in seven distinct neocortical brain regions from newborn to 95 year-old individuals[2]. Haug[3] estimated neuron density in 10–20 rows arranged perpendicular to the pial surface of the cortex in two to four areas per brain, multiplied by the assumed neocortical volume, and found an average of 15×10^9 neurons in the human neocortex. Haug found no decrease in total neuronal number with age and no difference in total numbers between males and females.

The three steps in estimating the total neuronal number in any defined brain region include: (a) delineation and estimation of the region's volume; (b) uniform sampling of the complex and irregularly shaped neocortex; and (c) estimation of the neuronal numerical density.

Based on unbiased principles, the Cavalieri method for the estimation of volume using systematic sampling and point-counting can be applied to any organ that can be cut into slices—physically or by means of optical or other scanning devices—and is independent of size or shape of the organ[4,5]. In a recent study by Regeur[6], neocortical volume, cortical thickness and volume of archicortex, the ventricular system, the central grey matter and white matter were estimated using stereological methods on brains from 28 old females (mean age 81.8 years) with increasing degrees of senile dementia, and brains from 13 (mean age 82.7 years) non-demented control females. Brains from the demented patients [14 Alzheimer's disease (AD) cases and 14 non-AD cases] had a smaller cortex volume and neocortical thickness was significantly reduced in the demented patients, with the highest degree of reduction in the most demented patients, as were the volumes of archicortex. No statistically significant differences were found in the volumes of cortex, white matter, central grey structures, ventricular volume or archicortex between the AD demented cases compared with the non-AD demented cases. The ventricular volume increased with increasing degree of dementia, but the difference between the demented group and the control group did not reach statistical significance. Surface area did not change in the demented patients, and no significant reductions were found in the volumes of white matter or central grey matter structures in the demented patients compared with controls.

In 1984 the dissector method was described, in which three-dimensional particles (e.g. neurons) are sampled with a constant probability without regard to size, shape and orientation of the particles, provided that two requirements are fulfilled: (a) the complete set of particle profiles hit by the dissector's planar transects should be identifiable; (2) the dissector positions are uniformly random in the complete reference region[7]. The method relies on the fact that one can, without any other assumptions at all, count a cell nucleus or any defined particle within a defined reference volume if it is present in a relatively thin section but not in the previous member of a pair of adjacent sections. Particles of arbitrary size and shape can only be sampled with equal probability using a three-dimensional probe, such as the dissector. Systematically sampling a subset of dissectors from the wide range possible in a serially sectioned brain region or central nucleus, taking each with a constant but arbitrary probability, is sufficient for the estimation of the total particle number or, as in this instance, nerve cells (for practical details and analyses of sampling design, *see* refs 5, 8–11). Williams and Rakic[12,13] have applied the same technique using the three-dimensional counting frame[14,15] to obtain estimates of neuronal numerical densities.

A method for uniform sampling in human neocortex combined with a modification of the dissector principle, the optical dissector, has been introduced[16]. With the optical dissector the procedure is performed in thick rather than thin sections, which makes it many times more efficient. Using this method, 94 normal brains were studied, 32 females and 62 males in age-groups 20–90 years[17]. An unbiased estimate of the total number of neurons in the neocortex was obtained simply by multiplying the Cavalieri estimate of the neocortical reference volume by the numerical density obtained with the optical dissector. The number of neocortical neurons in females was 19.3 billion, and in males 22.8 billion, a difference of 16%. The difference in the total number of neocortical nerve cells over the observed range of 70 years was 9.5%, providing an average "loss" of neurons of about 85 000/day. This possible age effect was the same for both sexes. The total number of neocortical neurons in the material varied more than a factor of 2 with a range of 118% (14.7–32.0 billion neurons) (see Figure 8.1). The natural variability in neuron number of 19% ($CV = SD/mean = 0.19$) in normal Danes thus represents a variance of more than eight times the variance of body height [CV (height) = 0.065]: $(0.19/0.065)^2 \approx 8$.

On average, there were 186 million more neurons in the left hemisphere than in the right and this difference was the same in the two sexes. Sex differences were found in the total volume, total surface and thickness of the neocortex, white matter volume, central grey structure and brain weight. With advanced age,

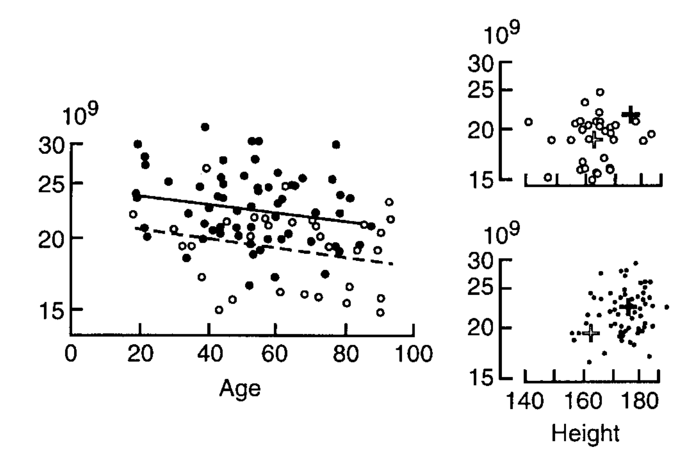

Figure 8.1 The number of neocortical neurons in normal Danes as a function of sex (●, males, ○, females) and age (left). The two orthogonal regression lines are indicated. To the right is illustrated the (absence of a) relation between the total number of neurons and the body height (cm) for each sex separately. The bivariate means for both sexes are shown in each diagram. All axes except the age axis are logarithmic

reductions occurred in neocortical volume, surface area, white matter, archicortex volume and brain weight, concomitant with a large increase in the ventricular system, while no change was found in grey matter volume and neocortical thickness. After sex and age were accounted for, neocortical neuron number was a dominating factor in determining the size of other brain structures. Neuronal density was not a function of sex or age.

A major problem in the interpretation of these data is evidently that one must take secular changes into account. Body height in Danish males has increased by approximately 9–10 cm from 1920 to 1980. Precisely *how* to correct for such changes is not known.

In conclusion, age may account for changes in both neocortical neuron number and neocortical volume without any effect on neuronal density. The reduction in cortical volume is seen without concomitant reduction in neocortical thickness, but only with consequence for surface area, a condition rather different from, for example, AD and AIDS, where the equally large atrophy only affects the neocortical thickness[17]. The largest changes in brain volumes are found in the brain white matters, with a reduction of ≈30%. In a recent paper by Tang *et al.*[18], the total length of the myelinated fibres in five elderly women of 86 000 km was statistically significantly decreased by 27%, compared with 118 000 km in five younger females. As expected, the ventricular volumes increased by 50%, which could at least in part be a white matter volume reduction.

More research is needed to give us knowledge of possible changes during development, ageing and disease. Serious development defects and diseases, such as mental retardation, AD, schizophrenia and AIDS, have all been shown to involve permanent structural brain changes. More information will help us to be able to separate the changes in normal ageing from those of neurodegenerative disorders and thereby understand the age conditioned functional deficits.

Potential Regeneration of the Ageing Brain

Stephen B. Dunnett

School of Biosciences, Cardiff University, Wales, UK

The brain does not spontaneously regenerate. As long ago as 1928, Cajal recorded that "once development was ended, the founts of growth and regeneration of axons and dendrites dried up irrevocably. In adult centres . . . everything may die, nothing may be regenerated"[1]. Although it remains the case that the damaged mammalian central nervous system (CNS) does not generally generate new nerve cells in response to disease or injury, the intervening 70 years have identified a considerable plasticity of axons to remodel nerve connections and a limited degree of neurogenesis, which opens new opportunities for promoting regeneration and repair in the damaged, diseased or ageing nervous system (see Figure 1).

COLLATERAL SPROUTING

The first clear evidence that Cajal's dictum was overly pessimistic in relation to the mammalian CNS came from the demonstration that if a septal cell loses some of its normal axonal inputs, then other afferent axons can sprout into the vacated spaces to form

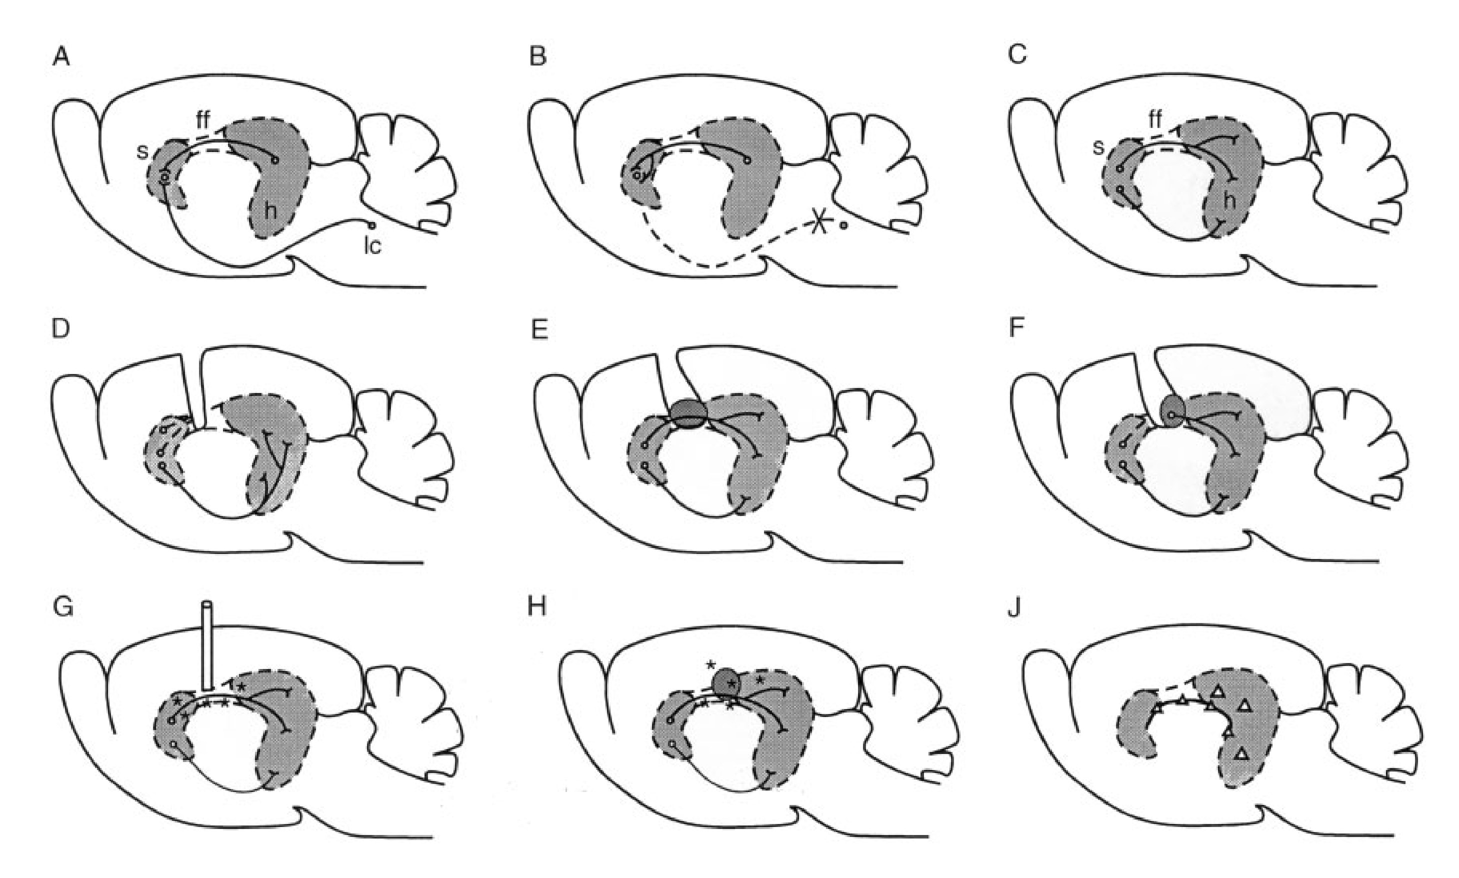

Figure 1. Schematic illustration of examples of regeneration and repair in the septo–hippocampal system of rats. (A) Normal synaptic inputs onto septal cells arising in the hippocampus and brainstem locus coeruleus. (B) Collateral sprouting of afferents from hippocampus following removal of afferents from the brainstem by a lesion of the medial forebrain bundle. (C) Normal septal projections into the hippocampus via dorsal and ventral pathways. (D) Compensatory collateral sprouting of ventral afferents following lesion of afferents to the dorsal hippocampus by transection of the fimbria-fornix bundle. (E) Implantation of hippocampal or glial grafts provides a substrate for regenerative growth of host septal axons back to the hippocampus. (F) Implantation of septal grafts provides a cholinergic reinnervation of the deafferented hippocampus. (G) Chronic injection of NGF molecules (triangles) diffusing via the lateral ventricles provides trophic support of cholinergic septo–hippocampal neurones in aged animals. (H) Implantation of cells engineered to secrete NGF provides similar neuroprotection in aged animals. (J) Neuronal stem cells in subventricular zone have the capacity to divide and differentiate in the adult brain. Whether they can also migrate to repopulate areas of cell loss in the aged brain remains speculative. ff, fimbria-fornix; h, hippocampus; lc, locus coeruleus; s, septum; small circles, neurones; small triangles, neuronal stem cells; asterisks, growth factor molecules

new synaptic connections with the target cell (Figure 1A,B)[2]. If the new inputs are from a different source, they are by and large not functional. However, collateral sprouting of spared fibres of the same systems can sustain functional recovery in a number of model circuits of the brain (Figure 1C,D)[3,4].

REGENERATIVE SPROUTING

A major problem for extensive axonal reorganization in the adult brain is that although axons can undergo a degree of local sprouting, they do not typically retain the developmental capacity for long-distance growth through the CNS to distant targets[5]. Long-distance growth of axons can nevertheless be promoted by providing an alternative substrate for growth, such as Schwann cells from the PNS, which can be used to bridge a gap caused by a lesion cutting a pathway or be implanted as a track along which new axons can grow (Figure 1E)[6].

NEURAL TRANSPLANTATION

When essential populations of neurons are lost, they may be replaced by transplantation. The techniques are now well established for transplantation of embryonic cells derived from the CNS into the aged brain of experimental animals (Figure 1F) and such grafts have been demonstrated to survive, repopulate areas of denervation, replace deficient innervations and restore lost functions in a wide variety of model systems[7]. There is now compelling clinical evidence that such grafts can provide a substantial alleviation of symptoms in Parkinson's disease[8], and clinical trials are now underway in Huntington's disease, spinal cord injury and stroke[9–11]. It remains a matter of speculation whether neuronal transplantation can alleviate the more diffuse and widespread degeneration associated with ageing and the dementias.

TROPHIC SUPPORT

Neuronal connections are dependent upon trophic support from their targets, and neurodegenerative diseases of ageing may in part be attributable to a decline in growth factor support[12]. Thus, an alternative approach to prevention of progressive neurodegeneration, and to induction and guidance of regenerative axon growth, is to apply or replace identified trophic factors explicitly. For example, central cholinergic neurones, which decline in ageing, are dependent upon nerve growth factor (NGF) for trophic support. Prolonged injections of NGF into the ventricles of ageing rats can inhibit the progressive atrophy of septal cholinergic neurones and block the functional decline in the animals' learning abilities (Figure 1G)[13]. A similar strategy involving chronic central infusions of NGF has been attempted in a pilot experiment in Alzheimer's disease with only modest success[14]. A major issue to be resolved is how to deliver large trophic factor molecules—which do not cross the blood–brain barrier—to defined targets in the brain; the most powerful experimental techniques to date involve implantation of cells that are engineered to secrete the particular trophic factor molecule (Figure 1H)[15].

ADULT NEUROGENESIS

It was believed until very recently that all neurones of the mature nervous system are born in early development, so that once lost they are not replaced. It is now clear that there exists in the adult human brain a small population of resting "neuronal stem cells" with the capacity to both undergo further cell division and differentiate into both neurones and glia (Figure 1J)[16]. This opens the hope that such cells may be recruited for repair, either by isolation, expansion and differentiation into defined neuronal cell types *in vitro* and reimplantation, or by finding the means to induce their spontaneous division, migration to areas of cell loss and local differentiation into appropriate neuronal phenotype to replace lost target cells *in vivo*. However, it must be recognized that substantial technical and theoretical problems remain in translating such procedures into applications for repair in human ageing.

Although the repair of neurodegenerative damage associated with ageing remains experimental, rapid advances are being made in the techniques for inhibiting degeneration, promoting regenerative growth and replacing lost populations of cells. The pessimism that has for long surrounded the poor prognosis of brain damage in ageing and disease is being transformed to an optimism that these novel experimental approaches may find direct clinical application in the neurodegenerative diseases of ageing. Nevertheless, formidable technical problems still need to be overcome to transform theoretical prospects into practical therapies.

Hippocampal Changes and Memory Impairment in Normal People

John T. O'Brien
Wolfson Research Centre, Newcastle upon Tyne General Hospital, UK

INTRODUCTION

The nature of age-related cognitive deficits and their relationship to what is "normal", such as Alzheimer's disease (AD), remains a controversial area. It has long been recognized that decline in many aspects of cognitive performance occurs in the majority of individuals as they age. Most interest has focused on memory and various labels have been used, including "benign senescent forgetfulness (BSF)", "age-associated memory impairment (AAMI)", "aging-associated cognitive decline (AACD)"[1] and, most recently, "mild cognitive impairment (MCI)"[2]. MCI describes the condition whereby a subjective memory complaint is accompanied by objective evidence of deficits, usually 1.5 standard deviations below age-corrected norms for a standardized test. Such individuals are known to "convert" to clear AD at a rate of about 15% per year[3], in contrast to previous categories, such as BSF, when progression over time does not occur[4]. However, potential entities such as BSF, AAMI, AACD and MCI are still the subject of criticism, since it is unknown whether they represent a true disorder or a spectrum of the normal population mixed with those with early, and as yet undiagnosed, AD[5,6].

ROLE OF THE HIPPOCAMPUS

The hippocampus has long been known to be central to the human ability to learn new information, particularly for so-called episodic memory, i.e. memory for discrete events, and declarative memory, which is memory requiring conscious retrieval[7]. This contrasts with the role of the hippocampus in animals, which is known to be primarily involved in the formation of spatial memories. Recent evidence suggests that in humans the hippocampus does seem important in the acquisition of new spatial memories, as well as episodic memory, but is not the actual site of such spatial maps once they have been formed[8]. Differential functional organization of the hippocampus in time and space has been demonstrated[7], giving support to the view that the main role of the hippocampus in memory formation is in forming new memories by capturing the event itself, coding it in time and space and binding it together for subsequent processing. Other brain areas (particularly the parahippocampal cortex and the frontal cortex) are also important in forming new memories, especially for encoding[9]. In contrast, other aspects of human memory (e.g. semantic memory) appears not to be dependent on the hippocampus[10] although areas such as the anterior temporal pole and frontal lobe may be important[11].

RELATIONSHIP BETWEEN MEMORY IMPAIRMENT AND HIPPOCAMPAL CHANGES

While this has been reasonably well established for AD, the same is not yet true for using the memory impairment associated with ageing and conditions such as AACD, AAMI and MCI. An age-related decline in temporal lobe and hippocampal volume is found in most, although not all, studies[12–14]. Reductions in medial temporal lobe and hippocampal volumes and reduced perfusion and functional imaging in normal individuals with memory impairment have been described by some groups[15,16] but not others[17], while the excellent spatial memory of taxi drivers has been related to enlargement of the posterior hippocampus in one study[18]. Further research is clearly needed. Similarly, some find a strong correlation between the degree of memory impairment in normal elderly people and volumetric change on magnetic resonance imaging, while others do not[14,16,17]. More consistent is the finding that amongst those who already have memory impairment, reduced temporal and hippocampal volumes do predict those who will decline to develop dementia, as opposed to those who will not[19–22]. However, whether this is simply a reflection of the "contamination" of normal memory-impaired individuals and those with early AD remains unresolved.

Neuropathological data are limited, although MCI individuals may have Alzheimer-type pathology intermediate between those with AD and normals[23]. Another candidate for the cause of any hippocampal damage during ageing would be excessive cortisol excretion associated with ageing, which is known to be toxic to the hippocampus in animals and possibly in humans[24–26]. These remain important avenues for future research. However, other possibilities exist for the neurobiological basis of memory and other cognitive impairments in healthy individuals. Generalized brain atrophy is known to occur with ageing[27,28], whilst an increase in white matter burden, presumably reflecting vascular pathology, occurs and has been linked with cognitive impairment in some studies[29].

CONCLUSION

Despite the hippocampus being central to new learning in humans and the evidence that memory impairment and hippocampal changes occur with ageing, further evidence linking the two is still needed. Undoubtedly, new views on hippocampal function and topographical organization, the better definition of the role of other structures, such as the parahippocampal gyrus and frontal lobe, in different memory functions, combined with further longitudinal clinical, electrophysiological, imaging and pathological studies, will provide a clearer answer to this important question in the near future.

Neuroendocrinology of Ageing

R. A. Burns and Mohammed T. Abou-Saleh

Department of Addictive Behaviour and Psychological Medicine, St George's Hospital Medical School, London, UK

INTRODUCTION

Neuroendocrinology is the study of interactions between the nervous and endocrine systems. Such interactions occur via complex mechanisms involving the cerebral cortex, limbic system, brain stem, hypothalamus, pituitary and periphery with regulatory feedback by many hormones to the pituitary, hypothalamus and probably higher centres such as the hippocampus. Observations of neuroendocrine dysfunction and disorders of behaviour have helped to improve our understanding of mental illness and will be discussed later in this chapter.

Despite a surge of research over the last 25 years, many gaps remain in our understanding of neuroendocrinology, especially that of central secretion and neural control of hormone release. The complex interrelationships between monoamines, neuropeptides and hormones have not been elucidated[1]. Hormones such as insulin and cortisol, once thought to exist only peripherally, are now believed to have central functions as neurotransmitters or neuromodulators[2]. Neuropeptides such as opioids and vasoactive intestinal peptide (VIP) are found centrally and peripherally and some, such as thyrotropin releasing hormone (TRH), can be secreted from the same nerve terminals as classical neurotransmitters, thus also acting as neuromodulators[3]. Some neurotransmitters, once thought to act solely via the hypothalamus, may directly affect the pituitary, bypassing the hypothalamus[4]. The hypothalamus remains the fulcrum of neuroendocrine activity. In response to primarily central stimuli, the hypothalamus acts either: (a) via release of neuropeptide releasing or inhibiting factors into the portal circulation to the anterior pituitary; or (b) via the direct release of neuropeptides to the posterior pituitary. Thus adrenocorticotrophic hormone (ACTH), thyroid stimulating hormone (TSH), growth hormone (GH), follicle stimulating hormone (FSH), luteinizing hormone (LH) and prolactin are released from the anterior pituitary and vasopressin (antidiuretic hormone (ADH)) and oxytocin from the posterior pituitary. There is an intricate multilevel system of feedback mechanisms between adjacent and even distant steps in the process of hormonal secretion. Description of peripheral endocrine effects are beyond the scope of this chapter.

Like other systems, the neuroendocrine system undergoes a degree of decline during senescence, although by varying degrees and different mechanisms. Ageing may affect the neural control of hormones; the endocrine cells themselves, their hormones, hormone receptors and post-receptor events in target cells[5]. Most commonly there is a reduction in receptor cell numbers but hormone-receptor coupling mechanisms have also been implicated[6,7]. As some symptoms of hormonal disorder mimic the symptoms of advancing age it is not surprising that the hypothalamus and endocrine system have been linked as causative agents to the ageing process. Such organ system-based theories of ageing assume the presence of an "organal pacemaker" for ageing which initiates the chain of events seen in senescence[8]. The failure of organ systems, with the loss of homeostasis, is important to many of these theories. Some ideas have focused on more peripheral endocrine glands, e.g. the hypothyroid hypotheses, but there has been a more recent shift to central structures, such as the hypothalamus[9]. Dilman and others have proposed that an elevated hypothalamic threshold to negative feedback is an important element in the "deviation of homeostasis" after the completion of growth, and that a relative hypersecretion of, among others, growth hormone renders the internal environment inconsistent with survival by altering glucose and fatty acid metabolism and resulting in vascular disease, diabetes mellitus and other forms of morbidity[10]. Work by Frolkis *et al*[11] in Kiev has shown that the hypothalamo–pituitary axis plays a role in the regulation of RNA synthesis and in the induction of some enzymes of carbohydrate and protein metabolism. They found that these functions deteriorated with age and their work suggests that homeostatic and repair mechanisms may be influenced, which gives some support for an aetiological role for the neuroendocrine system in ageing. Possibly a more integrated theory involves a more circular mechanism. Genetic programming combines with the internal and external environment to result in impairment of all cells with ageing, including cells of the endocrine system. Impairment of the endocrine system alters homeostatic function and thus accelerates impairment of the remainder of the organism[4]. Given the complexity of the interrelationships within the internal environment, it is unlikely that the debate generated by these theories will be resolved in the near future.

Much of the initial research on ageing and endocrine function was with animal studies which, although helpful, may not be entirely applicable to humans, as there are important differences[12,13]. However, techniques such as immunoassay have enabled us to measure hormone levels directly in humans, but even with this technique a high level of quality control is essential, as is the reliability of measurement. In human studies, too, we must remember that most samples are cross-sectional and we are therefore measuring age *differences* rather than age *changes*; longitudinal studies are therefore desirable. Nevertheless, in spite of these difficulties, greater sophistication and reliability in our measurement techniques, as well as the ability to synthesize hypothalamic releasing factors, have enhanced our understanding of neuroendocrinology and the effect of ageing.

AGEING AND NEURAL CONTROL OF ENDOCRINE FUNCTION

As previously mentioned, the neural control of hypophyseal secretion is complex and involves both classical neurotransmitters and neuropeptides, with good evidence that different neurotransmitter systems interact to modulate neurosecretion. Noradrenaline, dopamine, 5-hydroxytryptamine (5-HT), acetylcholine, γ-aminobutyric acid (GABA) and opioid peptides may all directly affect hypophyseal secretion mechanisms, whilst cholecystokinin, vasopressin and other neuropeptides have facilitatory or inhibitory roles[14].

With ageing the secretion of neurotransmitters and receptor binding and *sensitivity* are altered[15]. Animal studies have suggested that the facilitatory effects of Ca^{2+} in neurotransmission may be reduced[16]. The overall brain content of noradrenaline is reduced, with many hypothalamic noradrenergic nuclei showing reduced noradrenaline concentrations with age, and adrenergic receptor sensitivity also appears to decline[17]. Dopamine receptor numbers are reduced, especially in the nigrostriatum. Acetylcholine metabolism also shows reduction[18] and, although reports of reductions of brain 5-HT concentrations have not been fully substantiated, there does appear to be a reduced amplitude of circadian serotonin rhythm and a gradual decrease of 5-HT_2 receptors with age in the cerebral cortex[19]. It is likely that changes occur in other neurotransmitter systems with ageing, further altering the balance of neuronal control of endocrine function. In addition, neuronal sensitivity to feedback loop mechanisms may be altered, as reductions in the concentration of rat hippocampal cortisol receptors have been reported[20]. Exactly how the effects of ageing upon neural mechanisms alter the functioning of subservient endocrine axes is not clear, but age-related changes in each neuroendocrine axis will be described below, with reference made to neural control mechanisms where appropriate.

AGEING AND HYPOTHALAMIC–PITUITARY PERIPHERAL ENDOCRINE AXIS

Morphologically age-related changes of the hypothalamus and pituitary are relatively minor. Calcification of the sella turcica may occur and animal studies have suggested an increase in intracellular lipofuscin, with a reduction in the volume of neuronal end swelling as well as in the number of hypothalamic neurosecretory granules[21]. Fibrosis with loss of basophil cells—hypophysis naviculare—may occur in the anterior pituitary. Functionally, changes may be more pronounced and for the sake of clarity we will deal with each hormonal axis separately, as age-related change is differential.

HYPOTHALAMO–SOMATOTROPH–SOMATOMEDIN AXIS

The secretion of growth hormone (GH) declines in ageing humans[22] with dampening of pulsatile GH release and loss of sleep- and exercise-induced swings. In addition, provocation tests suggest reduced GH reserve. The age-related changes, less pronounced in females, are due at least in part to reduced pituitary sensitivity to hypothalamic growth hormone releasing hormone (GHRH) and reduction of somatotroph numbers. However, reduction in sensitivity of α2 receptors is also implicated, as evidenced by a blunted response to clonidine, an α2 agonist[23]. Peripheral α2 receptor numbers have been found to be diminished. Altered catechol aminergic activity has been implicated in rats as administration of L-dopa reversed both mean and pulsatile GH levels[24]. Somatomedin levels also fall, and it has been postulated that reductions in GH and somatomedin may play a role in osteoporosis and other degenerative diseases in the elderly[25,26].

HYPOTHALAMO–HYPOPHYSO–THYROID (HPT) AXIS

The HPT axis also undergoes changes coincident with ageing with a balanced decline in thyroid hormone production and degradation[27]. In the elderly male, the overall secretion of thyroid stimulating hormone (TSH) is reduced and the response to thyrotropin releasing hormone (TRH) is blunted. This reduction is not marked and in females TSH levels may even increase with age[25]. Pulsatility of TSH is maintained and, although results are inconsistent more recent findings have suggested that diurnal variation is also preserved[29]. Healthy ambulatory ageing subjects show only a slight decrement in serum thyroxin (T4) levels. Thyroid binding globulin levels are unchanged but serum triiodothyronine (T3) concentration may be reduced by 10–20%, partly due to the age-related reduction in conversion of T4 to T3[30].

HYPOTHALAMIC–PITUITARY–GONODAL (HPG) AXIS

The HPG axis also undergoes gradual decline with age[31]. In men, primary testicular failure, possibly a result of reduced testicular perfusion, leads to a gradual reduction in testosterone levels, which becomes more marked after 60 years. Maximally stimulated testosterone, free testosterone and tissue testosterone are also reduced. Despite widespread variation, it is likely that such change is purely related rather than due to sedentariness or minor illness[32]. Reduced testosterone levels and elevated oestradiol (as a result of testosterone degradation in the skin and liver) may account for feminizing features, such as gynaecomastia, which may be seen in old men. Reduction of the feedback testosterone results in elevated levels of luteinizing hormone (LH) and follicle stimulating hormone (FSH) with age. However, sensitivity to negative feedback is increased at the hypothalamic level. The amplitude and frequency of pulsatile gonadotropin releasing hormone (GnRH) and luteinizing hormone releasing hormone (LHRH) are reduced, possibly as a result of neurotransmitter and neuromodulator changes, and pituitary sensitivity to releasing factors also appears to diminish. In ageing females, primary ovarian dysfunction occurs with shortening of the cycle length, depleted oestrogen and elevated FSH[33]. Oestrogen levels fall to around 20% of the premenopausal level and then remain relatively stable, with the primary source of oestrogens being from androgen conversion in adipose tissue as ovarian androgens continue to be secreted[34]. After the menopause, serum FSH and LH levels greatly increase to peak between 51 and 60 years and gradually decline thereafter. Animal studies have suggested increased pituitary sensitivity to LHRH but in humans it is not known whether the increased bioactivity of LH and FSH is as a result of greater pituitary sensitivity or high LHRH levels[35].

In both males and females, the production of adrenal androgens is reduced with senescence. Although prolactin levels are elevated in ageing rats and mice, it is unclear whether this is the case with humans, although recent evidence suggests a slight increase in elderly men and a slight fall in ageing women until the age of 80[36].

HYPOTHALAMIC–PITUITARY–ADRENAL (HPA) AXIS

The HPA axis is the best known and most studied of the neuroendrocrine axes because of its intimate involvement in the

response to stress[37] (see below). Overall, findings suggest a mild reduction, if any, in basal functioning but with an altered regulatory capacity, an important factor in the stress response. Plasma total cortisol, plasma cortisol binding, plasma and urinary free cortisol and plasma ACTH are unchanged. Diurnal variation of cortisol secretion persists but may occur later in the day. Both ACTH and cortisol show decreased responsivity to provocative stimulation in older individuals and a degree of loss of the inhibitory feedback response[38]. Several studies have shown attenuation of the cortisol response to ACTH, possibly as a result of altered functioning of ACTH-stimulated cAMP glucocorticoid receptors, whose numbers also diminish with age[39].

POSTERIOR PITUITARY

Morphologically, animal studies have revealed subcellular changes in the posterior pituitary. In humans, earlier evidence suggesting non-alteration of posterior pituitary hormones[40] must be tempered by the more recent evidence of a tendency to increased secretion of vasopressin in the elderly with elevated basal levels. Diminished secretion by ageing hypophyseal tissue is offset by elevation of vasopressin levels as a result of a reduction in renal tubule sensitivity to vasopressin[41]. Animal studies suggest that ageing may result in the loss of a particular group of hippocampal cells normally inhibitory to vasopressin secretion. Oxytocin levels also decrease with age.

AGEING AND STRESS

"Stress" may be defined in many ways but implies demands upon an organism threatening to overwhelm it and resulting in a physiological response. Human physiological responses to stress, either physical or psychological, are characteristic and involve initial adrenal medullary sympathetic activity which is later superseded by activity of the HPA axis during the "adaptation" phase. The HPA axis and its response to stress is outlined in Figure 9.1. Thus, in situations of stress, there is centrally stimulated hypersecretion of ACTH and cortisol, along with facilitatory vasopressin. The HPA axis also plays a major role in the homeostasis of stress and it has been postulated that it achieves this by blunting the organism's persisting and potentially harmful physiological reaction to stress. The repeated aetiological linkage of stress to psychiatric illness has led over the last 25 years to much investigation of the HPA axis in stress and psychiatric illness, resulting in a mushrooming of the concept of psychoneuroendocrinology or behavioural endocrinology and the search for neuroendocrine markers for psychiatric illness. The concept of the neuroendocrine interface as "the window into the brain", although not fulfilling initial expectations, has led to neuroendocrinological techniques becoming powerful research tools and valuable diagnostic aids in psychiatry[42].

With ageing it appears that the physiological stress mechanism becomes compromised and there is also evidence that stressful stimuli can accelerate ageing[43]. At the neurochemical level, rat experiments have suggested changes in monoamine metabolism and poor habituation to stress occurring with increasing age[44]. Such a loss of habituation may be a result of an age-induced reduction of benzodiazepine binding sites[45] (thus increasing vulnerability to anxiety-induced mechanisms) or may be a consequence of a reduction of inhibitory hippocampal cortisol receptor numbers[46]. Despite inconsistent findings there appears to be a diminished maximal response of the HPA axis to stressful stimuli, denoting a reduction in reserve capacity in ageing humans.

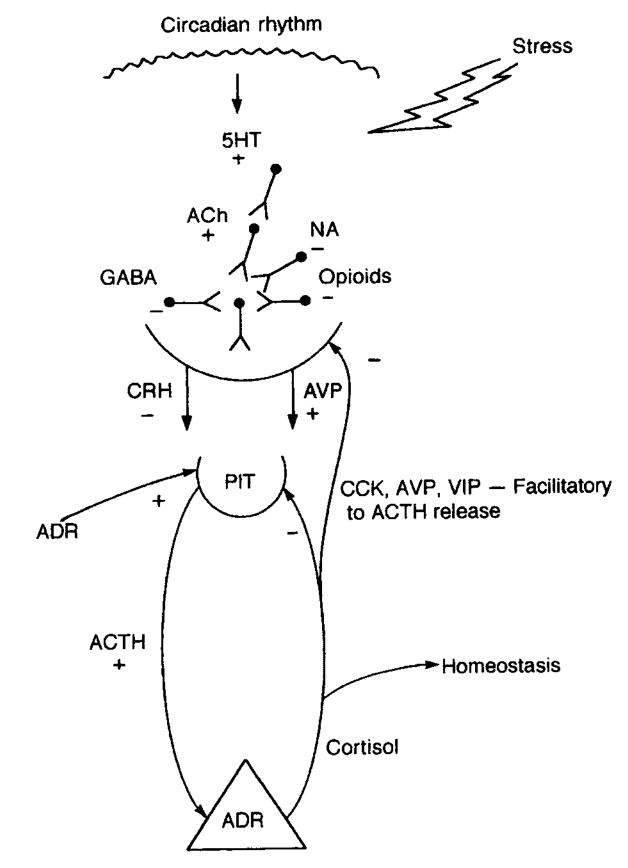

Figure 9.1 The HPA axis and its response to stress. 5-HT, 5-hydroxytrytamine; ACh, acetylcholine; NA, noradrenaline; GABA, γ-aminobytyric acid; CRH, corticotrophin releasing hormone; CCK, cholecystokinin; AVP, arginine asopressin; VIP, vasoactive intestinal peptide; ACTH, adrenocorticotropin; ADR, adrenal gland

AGE AND PSYCHONEUROENDOCRINE MARKERS

As a result of research carried out over the last 25 years, it is now firmly established that mental illness is associated with a high incidence of endocrine abnormality in both young and old. The most commonly investigated endocrine axis in psychological disturbance is the HPA axis, which in depression characteristically shows hyperactivity with elevated circulating ACTH-cortisol and non-suppression by dexamethasone, a powerful synthetic steroid that, in normal individuals, inhibits the secretion of ACTH and hence cortisol. In younger individuals, dexamethasone non-suppression is not truly specific for depression and is common in other affective psychosis and acute schizophrenia, with a lower incidence in anxiety, panic disorder and anorexia nervosa[47]. Dexamethasone suppression is also influenced by age (among other variables), with the healthy elderly showing a tendency towards non-suppression. However, non-suppression is more pronounced in the elderly depressed and those with Alzheimer's disease. In the elderly, as in the young, the dexamethasone suppression test (DST) is still a useful aid when used with careful clinical assessment[48]. It is helpful in differentiating depressive illness from minor psychiatric conditions and chronic schizophrenia, and reports have also suggested uses in identifying depressive pseudodementia and demented patients with depression[49]. In depression, the DST is a good predictor of long-term outcome, with greater risk of relapse in non-suppressors[50]. The

TSH response to TRH is also frequently blunted in depression but once again there is considerable overlap with other psychoses and there is an increased tendency to a blunted response in healthy senescent individuals[51]. Reports that blunted TRH responses are more pronounced in elderly depressives have not been entirely confirmed[52]. Growth hormone response to clonidine, an $\alpha 2$ agonist, is blunted in depression, Alzheimer's disease and ageing. Recent data suggest that this blunting is again more pronounced in elderly mentally ill subjects than in the normal elderly[53].

CONCLUSION

Overall, although it is only in recent years that neuroendocrine function in the elderly has been studied in depth, it has been established that significant alterations in function occur with ageing in humans. Some of those changes may approximate endocrine abnormalities observed in younger individuals with mental illness, most notably depression. As yet our knowledge remains limited in the realm of behavioural neuroendocrinology, but such similarities in function of the aged and depressed have led to speculation of some common mechanism underlying age and mental illness. Hopefully research into such speculation will provide further enlightenment.

Neurophysiology of Ageing as Reflected by Electroencephalogram (EEG) and Event-related Potentials (ERPs)

D. H. R. Blackwood, W. J. Muir and H. Förstl*

*Royal Edinburgh Hospital, Edinburgh, UK, and *Technical University, Munich, Germany*

INTRODUCTION

The electroencephalogram (EEG), which represents the electrical activity of the brain as recorded from electrodes placed at various positions on the scalp, is essential for the diagnosis of the epilepsies and the study of sleep disorders. It can also be a useful non-invasive aid for the detection and localization of structural brain abnormalities and the diagnosis of diffuse encephalopathies in patients with fluctuating levels of consciousness. Many of these conditions are common in the elderly population and it is therefore important to have a full understanding of the effects of normal ageing on the EEG, so that the significance of abnormal findings in elderly subjects can be more clearly interpreted.

ROUTINE EEG

Using standard procedures[1], electrodes, prepared with conductive jelly, are placed on the scalp and positioned in rows over frontal, temporal, parietal and occipital regions, according to the International 10-20 System[2]. Most recording equipment permits an easy selection of different montages of electrode pairs and the filtered and amplified potential differences between pairs of electrodes are then recorded on paper trace (qEEG) and stored for quantitative analysis. Recordings are usually obtained from several scalp regions and under different physiological conditions. The resting EEG is recorded with the subject's eyes open and for a period with the eyes closed to test the responsiveness of background activity. Routine inspection of the EEG waveform takes account of changes in frequency, amplitude and response to activation procedures such as hyperventilation, which may be employed to accentuate certain EEG abnormalities. The presence or absence of paroxysmal activity will be noted. For the detection of brain abnormalities, changes in frequency are generally more reliable than changes in amplitude. By convention, four frequency bands are described: EEG waveforms in the range 8–13 Hz denote the alpha range, which is commonly observed in occipital brain regions of young persons during wakefulness when the eyes are closed (alpha is attenuated by visual attention). There is wide normal variation in the alpha rhythm, and slowing occurs with normal ageing, delirious states and metabolic disorders. If frequencies greater than 13 Hz are present, the EEG is said to show beta rhythm. Such fast activity may be found in normal people but is also increased by some drugs, including benzodiazepines and barbiturates. At the lower end of the spectrum, activity in the range 4–7 Hz is termed theta. Theta activity can be marked in young children, becoming less by the time of puberty. Frequencies below 4 Hz are grouped as delta activity. Theta and delta activity occur during sleep and are commonly found in neurological disorders whose slow wave abnormality may only be diffusely recorded, as, for example, in encephalopathies. Such slow wave bands also prevail when localized at electrodes overlaying space-occupying lesions.

THE ORIGIN OF THE EEG

The scalp-recorded rhythmic activity of the EEG is believed to be generated in the cerebral cortex, especially in large pyramidal neurones orientated vertically toward the surface of the scalp. However, rhythmic activity arising in subcortical regions, in particular in the thalamus, can be imposed on and modify the activity of these cortical cells via thalamo-cortical projections[3,4], so that the scalp-recorded EEG reflects changes in both cortical and sub-cortical structures. Much of the EEG variation usually detected can be attributed to hereditary factors. The early twin studies by Lennox *et al.*[5], showing that brain electrical cerebral activity is strongly influenced by genetic factors, have been amply confirmed[6,7].

EEG CHANGES WITH AGEING

The most widely reported changes in the EEGs of elderly subjects are the slowing of alpha activity and the onset of focal theta and delta waves over the temporal regions[8–12]. The changes are complex, as they affect the alpha, the slow wave and the fast frequency bands regarding both power and topographic distribution[13–15]. Other reported changes corresponding to age include a much diminished slow wave response to hyperventilation and an increase in the occurrence of spike paroxysms in elderly subjects with no clinical evidence of a seizure disorder.

It is not clear, however, which if any of these changes are the result of a neuronal ageing process *per se*, rather than being manifestations of mild subclinical degenerative brain disease, including, for example, cerebrovascular disease, which is more common in the elderly. Quantitative EEG changes of power or complexity can be employed for highly successful statistical

discrimination between demented patients and elderly controls[16,17]. Subtle cognitive impairment has been related to the presence of EEG abnormalities in some groups of otherwise healthy elderly subjects, supporting the view that many of the changes found in the EEGs of elderly subjects are due to specific subclinical pathologies[18]. No changes are observed in highly select groups of 'successfully aged' individuals[14,19].

NORMAL AGEING

In an early study on an elderly population, Silverman *et al.*[20] recorded EEGs of 90 healthy subjects aged over 60 and reported a diffuse slowing of the background rhythm in 26% and focal abnormalities in 43% of the subjects. These findings have been confirmed more recently[10,21,22]. The slowing of the alpha rhythm with age was clearly demonstrated by Hughes and Cayaffa[23], who recorded the EEGs of 420 subjects aged 5–80 years. All subjects had been hospitalized and had undergone extensive neurological assessment in order to exclude the presence of brain pathology. In this group, the alpha peak frequency, which, up to the age of 60, had been between 10–11 Hz, fell to 9–10 Hz in subjects aged over 60. Some authors, however, claim a decreased slow and an increased fast activity with ageing[24]. The annual changes in non-demented elderly are minimal compared to the alterations of alpha and theta power in demented individuals[25]. There is no correlation between alpha and theta power and the degree of brain atrophy in the non-demented elderly[26].

Hubbard *et al.*[27] examined the EEGs of 10 centenarians aged 100–105, seven of whom were healthy, with no clinical evidence of degenerative brain disease. In this group, posterior dominant rhythms were in the lower part of the alpha range, and slow wave foci over temporal regions were common. These changes were similar to those found in subjects aged 80, and the study provided no evidence for a progressive decrease in alpha frequency or for an increase in focal temporal slow waves in subjects aged 80–100 years.

Changes in the EEG of elderly subjects, which have been attributed to early cerebrovascular insufficiency, include a diminished response of slow-wave activity to hyperventilation and the development of focal abnormalities, particularly over the anterior temporal regions. In a young person, hyperventilation for a period of 3 or 4 minutes usually produces a gradual increase in diffuse slow activity in the theta and delta range, which settles back to standard level within approximately 1 minute after cessation of over-breathing. This response is age-dependent and is most striking in children, who display delta activity at very high voltages. In contrast, old people show diminished or absent response to over-breathing, which may, in part, be due to diminished alteration in P_{CO_2} when hyperventilating[42].

Bursts of rhythmic theta activity over the temporal regions frequently appear in late adulthood, and these are associated with cognitive and memory deterioration[18,28]. In a recent study, Visser *et al.*[29] measured the EEG and performed computed tomography (CT) brain scans in a group of clinically healthy subjects aged 65–83 years. In this group of elderly subjects, those with focal EEG delta wave activity, recorded over the left anterior temporal region, performed poorly on neuropsychological tests of word fluency (thought to address temporal lobe function) and also had significant ventricular dilatation measured on the CT scan. It was concluded that such left-sided temporal slow-wave abnormalities found in the EEGs of some elderly subjects may be a valuable early indicator of temporal lobe pathology.

The probability that the EEGs of average adults do not change much throughout life and may, indeed, be relatively normal in otherwise healthy centenarians is thus raised[27]. The slowing of EEG frequency with age could be explained by changes in cerebral blood flow. Regional cerebral blood flow shows a strong inverse correlation with the appearance of EEG slow waves and is directly correlated with posterior alpha activity[30,31]. A direct causal relationship between a reduced cerebral blood flow, an increase in slow waves and a reduced alpha frequency in the EEG of elderly subjects could, therefore, be postulated[32].

EVENT-RELATED POTENTIALS (ERPs) AND AGEING

Electrical cerebral responses to discrete stimuli, such as visual, acoustic or contact stimuli, cannot, by and large, be detected in the scalp-recorded EEG. Electrical response to such events is small in comparison to their cerebral background activity, and averaging techniques are required for their visualization. Such techniques have proved of enormous value to neurologists and psychiatrists studying brainstem and higher cerebral function, by permitting the detection of tiny voltages generated in response to specific stimuli. To extract the time-locked activity generated by a given stimulus, a repeated series of stimuli is presented, and epochs of EEG, captured after each presentation, are summed and standardized/averaged. The random background EEG will tend to decrease in amplitude on summation, whereas the desired event-related potential will remain the same in size.

EXOGENEOUS EVENT-RELATED POTENTIALS

ERPs offer a means to assess peripheral nerve and brainstem function by using different sensory modalities. Early evoked potentials, generated within about 80 milliseconds (ms) after a stimulus, are described as exogenous because they seem to depend on the nature of the stimulus itself rather than any subjective response the subject may make to the stimulus. Auditory brainstem potentials, generated within the first 10 ms after a clicking sound, are evoked in a routine procedure to provide information about the functioning of auditory nerve and brainstem structures in the auditory pathway. Somatosensory event-related potentials (ERPs), evoked by electrical stimulation of, for example, the median nerve at the wrist, include the median nerve action potential, recorded at the brachial plexus, and activity generated in neurones of the spinal dorsal horn and dorsal column. Later peaks probably reflect activity in the medial lemniscus and primary somatosensory cortex. Early visual evoked responses to light flashes reflect activity in the visual path between the retina and the visual striate cortex.

From the second to the ninth decade of life, there is a linear increase in the latency of exogenous potentials[33]. The latency of the median nerve compound action potential, recorded at the brachial plexus (the 'N10 waveform'), increases from an average of 10 ms in the second decade to approximately 12 ms in octogenarians. With few exceptions, a similar rise in latency with increasing age is found in all exogenous potentials of all three sensory modalities addressed and renders age corrections clinically important. The central conduction time of auditory evoked potentials (AEPs) increases by 1–4 ms/year, the latencies of visual evoked potentials (VEPs) by 2–4 ms/decade after age 40 years[34]. Many age-related anatomical, physiological and biochemical changes may contribute to the slowing of nerve conduction implied by these latency delays.

ENDOGENOUS EVENT-RELATED POTENTIALS

ERPs generated more than 80 ms after a stimulus may reflect the psychic condition of an individual. Such responses are termed

"endogenous" because their latency and amplitude are hardly influenced by the physical characteristics of the stimulus such as its intensity or frequency, but reflect how attentive the subject is. They also give an indication of the degree of complexity inherent in a cerebral cognitive or memory operation performed on exposure to a stimulus. The P300 response is one endogenous ERP that has been extensively studied, as it is thought to reflect the mental processes of selective attention, learning and memory. To generate a P300 response to an auditory stimulus, the subject is required to attend to a series of low-pitched (non-target) tones, randomly interspersed with high-pitched (target) tones. The recognition of these target tones generates a positive potential, which can be recorded widely over the scalp at approximately 300 ms after the auditory stimulus. The P300 response to the target stimuli is much more explicit, and it is generated only when the subject concentrates on the task; its amplitude is thought to reflect the level of attention and its latency the processing time involved in the recognition of a target tone.

EFFECT OF AGE ON LONG LATENCY EVENT-RELATED POTENTIALS

The latencies of all endogenous event-related potential components appear to increase with age from the second decade onward, a fact that led to extensive research activity in relation to the auditory P300 component[35–41]. Some authors have reported a linear increase of P300 latency with age up to senescence with an increase of 1–2 ms/year. However, comparative studies, comprising large numbers of controls, have found an exponential ageing effect with a much higher rate of increase (of up to 4 ms/year) in P300 latency in subjects older than 60 years as compared to younger adults[37,39,41]. P300 latency is also increased in the presence of a variety of brain pathologies, including the dementias of Alzheimer's disease and cerebrovascular disease. In elderly subjects, it is difficult to separate the effect of ageing *per se* from the effects of subclinical degenerative or vascular changes on endogenous event-related potentials, and this is equally true for routine EEG. In a clinical environment, where P300 measurements may be useful, for example in dementia and schizophrenia, it is essential to carefully match individuals for age, particularly if elderly individuals are concerned.

Pharmacokinetic and Pharmacodynamic Considerations in Old Age Psychopharmacology

Fabrizio Schifano

St George's Hospital Medical School, Department of Addictive Behaviour and Psychological Medicine, London, UK

The elderly have the highest incidence of medical and psychiatric disorders. These conditions frequently occur simultaneously and are often chronic, lasting the lifetime of the individual. Consequently, the elderly require more medication than younger patients and even consumption of "over-the-counter" drugs is considerable among the aged[1]. Because of this multiple drugs administration, they frequently experience adverse side effects. Psychotropic drugs have often been involved in such interactions, and cause twice the incidence of side effects in elderly patients as they do in younger patients[1]. Drug interaction can produce a change in the pharmacological effect of a drug by altering activity at the site of action (a pharmacodynamic interaction), or by changing the plasma concentrations of a drug (a pharmacokinetic interaction), or both.

On the other hand, there has been a tendency of drug studies to focus on younger age groups and to exclude patients with co-morbidity or polypharmacy[2]. As a result, the generalization of current drug trials is a problem in old age psychiatry. Moreover, older adults respond less predictably than younger adults to most medication and this unpredictability is particularly evident among the frail elderly, who often suffer from central neurodegenerative disorders[3].

For these reasons, physicians treating patients with multiple medications may be overly concerned about the potential risks of treatment and deny the patient the chance of recovery[4]. Physicians should, however, remember that response is generally good for elderly people who have specific psychiatric disorders, as is the case with major depressive episodes, and that the risks of leaving the client untreated could be greater than the potential risks of treatment.

Although treatment of the elderly may be complex, with some knowledge of both the pharmacodynamics and pharmacokinetics basics it is something that is both manageable and rewarding. In this chapter, the changes in the effect of psychotropic drugs with aging in general terms will be highlighted.

PHARMACOKINETICS

With aging, changes can occur in one or more of the different pharmacokinetic parameters; absorption, distribution, metabolism and excretion.

Absorption may be slower in the elderly or delayed in onset and this is due to several factors: reduction in gastric pH, diminution of the size of the intestinal absorption area, reduced mesenteric blood flow (in general, the flow to all organs is diminished because of a decreased cardiac output). As a final consequence, the oral bioavailability of drugs may decrease in the elderly[5].

Distribution is grossly influenced by the composition of the body; the volume of distribution may be increased in elderly patients due to a greater percentage of adipose tissue[6]. Most of the psychotropic drugs (and especially sedatives, such as benzodiazepines) are stored in fat tissues and this constitutes a contributory factor for the significant elimination half-life increase that is usually observed in the elderly. In fact, the elimination half-life is determined by clearance (which is the rate of drug removal per unit of plasma concentration) and by volume of distribution itself. The higher the volume of distribution and/or the smaller the clearance, the longer will be the elimination half-life. Moreover, both the lean body mass and the bodily water[7] are decreased, so that ethanol (which is usually distributed across the bodily fluids) will show a higher concentration in the elderly than in younger groups[8]. Plasma protein binding is decreased in the elderly[1] because albumin concentration falls significantly. As a result, an increase in the free (non-bound) drug fraction in the plasma (the one that is able to pass the blood–brain barrier, but also the one that can determine the possible side effects) is observed. On the other hand, distribution of drugs into the brain may be decreased simply because cerebral blood flow (especially in arteriosclerotic patients) is usually diminished.

Metabolism. For psychotropics (lithium being the only notable exception), the most important metabolic processes are carried out in the liver (and elimination of metabolites will be made with faeces). As happens with most organs, the hepatic blood flow is diminished with age. The *metabolic transformation* processes are carried out by the microsomal enzymes in two different ways: hydroxylation and demethylation (processes that are significantly reduced with age) and conjugation with glucuronic acid (a process that is relatively unaffected in the elderly). This explains, for instance, the observation that benzodiazepines such as oxazepam and lorazepam (their major metabolic pathways involve glucuronidation) do not show clinically significant changes in pharmacokinetics with age[9]. On the other hand, chlordiazepoxide, diazepam and all the other pronordiazepam-like compounds (i.e. those that have *N*-desmethyldiazepam as the major metabolite) will show an increase of elimination half-life with age. In fact, these drugs are not metabolized by glucuronidation in the liver and, as a result, administration of these compounds in the elderly may cause a prolongation of action after a single dose and delayed accumulation on multiple dosing in the elderly[10].

Metabolic interactions usually take place in the liver and are of special interest, as multiple drugs prescription is common in advanced age. The genetically polymorphic cytochrome P450 2D6 (CYP2D6) is responsible for the metabolism of several psychotropics. CYP2D6 activity does not change with age[11]. CYP2D6 activity may be impaired by inhibitors such as paroxetine and fluoxetine[12], which can result in non-linear plasma drug concentration kinetics, as well as drug interaction when other drugs metabolized by CYP2D6 (such as desipramine, nortriptyline, neuroleptics, carbamazepine) are co-administered. Differently from paroxetine, fluoxetine and norfluoxetine (fluoxetine major metabolite), with sertraline the same pharmacokinetic parameters are found in both the young and the aged. Moreover, sertraline has much weaker inhibitory effects on CYP2D6[12].

Average dose adjustments for the aged can be derived from a simple equation and mean pharmacokinetic parameters from older and younger adults. However, individual dose adjustments (large variations in the decline of organ functions is possible) can be obtained from the drug clearance in a particular patient, where clearance/fractional bioavailability may be calculated from the area under the curve (AUC) of the drug in question[5].

Excretion. Advanced age reduces renal function[6], with important implications for lithium prophylaxis. The most important pharmacokinetic change in old age is a decrease in the *excretory capacity* of the kidney, so that the elderly should be considered as renally insufficient patients[5]. Since lithium is excreted in the urine, guidelines for lithium prescription recommend using a single bedtime dosing regimen[13]. Due to these considerations, an implementation of specialized clinics to manage and monitor elderly patients maintained on lithium has been proposed and discussed.

PHARMACODYNAMICS

Provided that pharmacokinetic guidelines for these adjustments are taken into consideration, the same plasma concentration is achieved in the elderly as in the young adults. However, we are frequently confronted with pharmacodynamic changes in old age that alter sensitivity to drugs, irrespective of changes of drug disposition[5].

The central nervous system (CNS) is especially vulnerable. For example, aging can alter the sensitivity of the GABA carrier to some anesthetics (e.g. propofol and etomidate[14]). Moreover, in a well-known study[15] the effects of a single 10 mg dose of nitrazepam were compared with a placebo in healthy young and old people. Elderly people made significantly more mistakes in the psychomotor tests than the young, despite similar plasma concentration and elimination half-lives in both groups. The difference is probably explained by an increased sensitivity of the aging brain to the action of nitrazepam. It has been proposed[16] that, with advancing age, and prematurely in Alzheimer's dementia (AD), the declining mitochondrial ATP synthesis increases GABA synthesis (a factor possibly responsible for forebrain dystrophic axonal varicosities, losses of transmitter vesicles and swollen mitochondria, markers currently regarded as earliest signs of aging and AD). Moreover, the particular vulnerability of the elderly to sedatives could be explained by aging-related changes in the expression of the gamma (2S) and gamma (2L) subunits in various brain regions, which suggest the existence of aging-related changes in the sub-unit composition in the GABA-A receptors, which in turn might lead to changes in receptor pharmacology[17]. Lastly, it seems that the activity of GABA-A transaminase (an enzyme that degrades GABA to succinic semialdehyde) is inhibited, which results in elevation of GABA content in the brain in some age-related neuropsychiatric disorders such as AD[18].

The elderly are particularly sensitive to drug-induced parkinsonism[19], which can reflect decreases with age in *dopamine* (DA) turnover and the suggested[20,21] age-dependent deficit of the dopaminergic system, presumably related to a reduced number/activity of nigrostriatal and mesolimbic neurons. In humans, an age-related decline of binding of a ligand for dopamine transporters, specifically to the striatum, has been found, at the rate of 6.6% per decade[22].

The response to agents with strong anticholinergic properties (tricyclic antidepressants; classical antipsychotics) increases in old age and may be accompanied by impairment of intellectual capabilities, agitation and, ultimately, delirium[23]. However, non-demented elderly patients with psychiatric problems seem to tolerate psychotropic drugs (with respect to the impact on their cognitive competency) much better than patients with AD[24]. Age-related reduced responsivity of the cholinergic system in the hippocampus has been well documented[25], but also disturbances in GABAergic/cholinergic interaction may play a key role in age-related cognitive dysfunction[26]. During aging, higher affinity nicotine binding in the frontal cortex and the hippocampal formation decreases and these reductions may predispose the neo- and archicortex to the loss of nicotine *acetylcholine* receptor proteins observed in age-associated neurodegenerative conditions[27].

Studies in humans and primates suggest that the aged brain is prone to the degeneration of the locus coeruleus (LC)[28]; the ascending dorsal noradrenergic bundle of the LC is involved in cognitive processes such as memory, learning and selective attention. Moreover, a profound *noradrenaline* depletion in the pre-frontal cortex (an area involved in certain cognitive functions, such as prevention of distractability by irrelevant stimuli) has been described in the elderly[29]. Together with the partial loss of CNS noradrenergic neurons, a compensatory activation of remaining CNS noradrenergic neurons has been described[30], which can explain the enhanced responsiveness (both in normal older subjects and with patients with AD) to noradrenergic agents such as yohimbine[31].

The central serotonergic system is also adversely affected by aging, so that it has been proposed that possible reduction in humans of 5-HT_{2A} receptors and *serotonin* reuptake sites may contribute to ethanol consumption, depression and cognitive dysfunctions frequently seen in the elderly. These changes may alter the effectiveness of serotonergic drugs[32,33].

During the normal process of aging a number of changes in the glutamatergic system (involved in processes such as motor behavior, cognition and emotion), and especially a decrease in the density of *glutamate* NMDA receptors, have been described[34]. Glutamate interacts with other neurotransmitters to conform the substrates of specific circuits of the brain that are relevant to aging. Impairment of intracellular energy metabolism associated with hyperactivation of glutamate receptors may contribute to the neuronal death seen in neurodegenerative disorders[35]; the extent of glutamate neurotoxicity in the hippocampus is highly age-dependent, with mature animals' hippocampi more vulnerable to glutamate-induced cell death[36].

On the whole, aging is associated with changes in the regional brain chemistry and the brain multi-chemical networking profile (MCNP). In fact, there is an increase in overall chemical correlation in MCNP within and across all brain regions with increased age. This increased correlation may reflect an adaptive or compensatory response (possibly related to the elongation of the dendrites with aging) to the reduced levels of regional brain chemicals[37]. Lastly, a diminished efficiency of the homeostatic mechanisms has been described in the aging brain, in part because of the reduced activity of various neurotransmitter systems. Counter-regulatory processes are therefore reduced and reactions to drugs may be increased[23].

PRACTICAL ISSUES

Bearing in mind the above-described pharmacokinetic and pharmacodynamic changes of psychotropic drugs in the elderly, a few principles could be recommended as prescribing guidelines[38]: one should become familiar with a number of preparations and preferably administer them; use as few drugs as possible (including drugs for non-psychiatric conditions); 'keep it as simple as possible': give written instructions; avoid depot-forms, the treatment should be started in low dosages (1/5 to 1/4 of average adult dosage) and slowly increased (no sooner than every 5–7 days[39]); the maintenance dosage is about 1/3–1/2[40] of average adult dosage ('start low and go slow'), but some elderly patients might need and can tolerate full doses[8]. The times required to reach steady-state therapeutic levels are longer.

Moreover, it ought to be emphasized that some psychotropics are more suitable for the elderly than others. For the treatment of affective disorders, *tricyclic antidepressants* are efficacious and inexpensive, but *SSRIs* and newer antidepressants are better tolerated and safer in overdose[41]. With respect to the putative diminished 5-HT responsivity in this population, the ability to identify SSRI non-responders via 5-HT challenge in combination with neuroimaging measures may have important clinical utility[33]. Among the SSRIs, preference is possibly given to sertraline[12]. The selective *MAO-A inhibitors* have not been extensively studied in the elderly, but they have definitely overcome the use of the classical MAO inhibitors. *Lithium* is still the mainstay for the treatment of bipolar disorders, but careful dosage and monitoring of plasma concentration are necessarily required. On the other hand, bipolar elderly patient responders to *valproate* ought to achieve higher serum concentrations of valproate itself[42].

The age-related changes in the pharmacokinetics and pharmacodynamics of the *benzodiazepines* (still the most frequently prescribed drugs for anxiety in the elderly) recommend preferential use of those agents that are metabolized via conjugation (oxazepam); *risperidone* (which is better tolerated in the elderly) may be used as an alternative. However, together with the sedation increase, with a sedative/hypnotic prescription a cognitive function decrease is observed in the elderly, with consequent risks of falls and injury (especially if the diazepam-equivalent dosage is higher and if the patient is prescribed with more different drugs)[43]. According to some suggestions[44], because of the high level of comorbidity between generalized anxiety disorder and major depression in late life and the observation that anxiety is usually secondary to depression, antidepressants constitute the primary pharmacological treatment for many older people. For the treatment of insomnia, both zopiclone and temazepam are to be considered as effective hypnotics, but the first shows a superiority on sleep architecture[45]. New promising agents, such as *cholecystokinin-B receptor antagonists*, seem to be specific, in aged animals, for an improvement of sleep quality[46]. For the treatment of psychotic syndromes, due to the elderly extreme sensitivity to parkinsonian side effects and to the anticholinergic properties of the *classical antipsychotics*, attention is given to the *newer antipsychotics*, but there is still a paucity of data. Clozapine may be a useful drug but adverse effects can occur[47].

Notwithstanding the aforementioned I am in agreement with Jovic[38], who stated that "psychotropic drugs cannot compensate for the lack of human contacts, devotion and intensive relationships, but complement them".

Normal Ageing—A Problematical Concept

D. B. Bromley

Department of Psychology, University of Liverpool, UK

INTRODUCTION

The word "normal" is used to refer to what is statistically normal, that is within the average range. The range can vary somewhat, say from the middle 50% of a normal distribution to perhaps the middle 80%, depending upon one's purpose. The word is also used to refer to prototypical members of a category, members with characteristics that best exemplify the category as a whole. The word is used to refer to what is socially prescribed and expected, such as the usual forms of appearance and behaviour for a given occasion in a community. Another usage refers to a standard pattern or sequence of events that have a high probability of occurrence, such as impairment of vision and hearing in later life.

NORMAL AND PATHOLOGICAL AGEING

With regard to human ageing, the word "normal" is used in all the above senses, depending upon the context. In professional gerontology, however, the phrase "normal ageing" usually implies the existence of a contrasting condition or process, viz. "pathological ageing". Difficulties arise because normal ageing and pathological ageing are conceptually interdependent. The main historical landmark in attempts to distinguish between them was the publication of Korenchevsky's *Physiological and Pathological Ageing*[1]. Korenchevsky drew attention to the fact that some physiological functions in some elderly human subjects were equal to or superior to those of chronologically younger subjects. Psychological research into sensorimotor and cognitive performance often reveals that some elderly subjects perform as well as or better than the average younger subject.

On the basis of evidence that some individuals show relatively little physiological impairment with age, at least until late life, Korenchevsky inferred the existence of primary (non-pathological) ageing. On the basis of evidence that other individuals show substantially greater than average impairment earlier in adult life, he inferred the existence of secondary (pathological) ageing.

These two inferences, however, are simply two versions of the same argument, namely, that ageing is characterized by wide differences between individuals. If we plot the distributions of scores on physiological or psychological functions for several age groups in a cross-sectional study, we often find considerable overlap between even widely spaced age groups. If the distributions of performance scores for the same respondents at different ages in a longitudinal study are compared, we usually find that individuals tend to retain their position (rank order) relative to other respondents. A minority, however, show decline relative to their position at earlier ages. These are the people who appear to exhibit pathological ageing. Thus, individual differences in normal ageing tend to be maintained, even though there is a decline with age, on average, over the period studied. These differences are brought about by various causes, including genetic characteristics, life-history events, life styles and environmental conditions.

Even among the community-dwelling elderly, there are wide variations in physical and mental health and wide variations in such things as living conditions, social support, stress and coping strategies and health. In a multicultural society, the range of differences between individuals at later ages is likely to be very wide. The process of normal ageing is a social as well as a biological process. That is to say, society *prescribes* or *normalizes* various stages in the life cycle, so that there are typical ages for the completion of full-time education, marriage (or sexual partnership), parenthood, occupational status and retirement. Such arrangements may change from one generation to the next. This, together with secular changes in health, longevity, life styles and so on, make the concept of "normal ageing" a moving target. Flynn has reported substantial secular (cohort) effects on measures of intelligence[2]. Consider how the contraceptive pill and hormone replacement therapy have changed the life styles of women. Consider also how drugs, AIDS, migration and economic factors may affect ageing in sections of the population. These are technical issues for demography and epidemiology.

It is possible to demonstrate general age trends and effects. For example, the sex difference in longevity is well established; there is a differential decline in fluid and crystallized psychological abilities; anatomical and physiological functions have their characteristic normal patterns of change with age. There are some similarities between the normal (common) effects of ageing and the effects of pathologies such as Alzheimer's disease, as shown by neurological and psychological tests. These trends and effects are compatible with the view that ageing is the result of a multiplicity of causes. They are not proof that there are two sorts of ageing: pathological and normal (non-pathological)[3]. On the other hand, there is the question of whether senile dementia of the Alzheimer type or multi-infarct dementia are the end-results of a normal intrinsic ageing process that would affect anyone who lived long enough, or whether they are abnormal conditions induced by genetic faults, life-history factors or specific extrinsic causes, such as infection or exposure to noxious substances. Genetic mutations increase with advancing age, and may affect performance before the obvious signs and symptoms of disease.

The argument in favour of the notion that there are two sorts of ageing—normal and pathological—is supported by evidence that people suffering from identifiable pathologies, such as cancer, heart disease or diabetes, have reduced life expectations and are

functionally less competent in some respects (see van Boxtel *et al.*[5]). Moreover, some of these disorders are age-related; some, such as Simmonds' disease, mimic the normal (usual) effects of ageing. Individuals who survive to a late age do not have a history of such disorders. The difficulty with this argument is that it is circular: pathological conditions are conditions that increase the likelihood of functional impairment and death; conditions that increase the likelihood of functional impairment and death are pathological. If an adverse effect commonly associated with age is not attributable to pathology, then, by definition as it were, it is ''normal''. If the underlying cause is identified, it is then labelled ''pathological''. Diseases can be regarded as concepts rather than entities (unless a cause can be found), in which case the distinction between normal and pathological ageing is a matter of definition, not an empirical issue. The empirical issue is how to identify and deal with the many age-related causes of impairment, regardless of whether they affect many people or just a few.

In order to demonstrate the existence of pathological ageing (as distinct from pathologies that increase functional impairment and the probability of death), we would need to show stepwise discontinuities in age trends, or departures from the ''normal'' distribution of differences in performance. Stepwise discontinuities and bimodal distributions are not common in the sorts of samples recruited for cross-sectional or longitudinal research in ageing.

Defining pathology in terms of a marked deviation from normal function means that the cumulative adverse effects of ageing eventually become pathological relative to standards for younger people but not older people—hence the view that there are many normal old people but few healthy ones! Stoller reported a tendency for older people to interpret their symptoms in terms of pain, discomfort and interference with their activities, rather than in terms of a possible medical condition[5].

Improvements in living conditions, diet, exercise and medical treatment have the effect of extending the average span of life, and so have the effect of redefining what we mean by normal and pathological ageing[6]. The distinction between the ''young old'', and the ''old old'' is now well established. Normal ageing can be taken to mean that set of intrinsic age-related effects that characterizes the adult life of people who occupy the middle ground of a distribution of age at death, or that characterizes and explains the average elderly person's functional competence. Pathological ageing can be taken to refer to the intrinsic age-related effects that characterize people who die relatively young, or who perform well below comparable people of the same age, as a consequence of these effects. The problem here is to demonstrate a causal connection between age-related ailments and the so-called ''intrinsic'' effects of ageing.

Normal or intrinsic ageing can be regarded as a species-specific process of degeneration, subject to a degree of variability depending upon initial genetic endowment and subsequent environmental conditions. Pathological ageing is any substantial deviation from the normal (standard or common) pattern of age-related changes.

THE CAUSES OF AGEING

When we examine the distribution of age at death for human populations, we find a relatively ''normal'' distribution on which is superimposed a ''tail'' representing infant mortality, accidents and premature deaths in early adult life. A normal distribution is typically the result of a multiplicity of independent contributory causes. The distributions of scores for physiological and psychological functions, obtained from reasonably large samples of the sort usually recruited in studies of ageing, tend to be relatively normal. So the assumption is that these effects, too, are the result of a multiplicity of independent causes. The aim of such studies is to identify the factors that account for most of the observed variation[7,8]. In some research studies, gender, education, health and intelligence account for a substantial part of the variation in psychological performance, leaving chronological age accounting for little.

The existence of trends and effects associated with chronological age does not imply a causal agent—''ageing''. As we have seen, ageing is simply a convenient label for a variety of age-related primary and secondary causes of impairment. Some of these causes no doubt interact and produce many sorts of indirect and long-term effects. For example, injuries, stresses, learning experiences and many other eventualities can occur at different ages. They may have different consequences because other age-related changes have or have not taken place, and because of differences in people's biological, psychological and social characteristics. In any event, given the complexity of the processes involved in human ageing and the long periods of time over which the processes occur, a considerable amount of ''turbulence'' in the effects of ageing is to be expected. Even small differences in initial personal characteristics and circumstances could lead to wide differences, in physical and mental health and performance, between individuals at later ages.

On this view, older people who are physiologically and psychologically very competent are simply those who have a superior biological constitution, have suffered fewer or less serious adverse effects from the many age-related causes of impairment, and have been able to take advantage of circumstances that promote health and well-being. People who survive to very late life with high levels of physiological and psychological competence are sometimes referred to as a ''biological elite''. Such people occupy, say, the top 10% of a distribution of physiological or psychological performance. They are studied retrospectively in the hope of identifying some of the factors that contribute to longevity and functional competence in late life.

Older people at the other end of the distribution are those who have not had the same benefits, and are regarded as suffering from one or other of the disorders of late life. On this view, the elderly who occupy either the upper or the lower tail of a relatively smooth normal distribution are different only in degree, not in kind, from those that occupy the middle ground. Of course, future research may identify specific positive and negative factors that will help us to account further for the observed variations in longevity, health and performance.

BASIC RESEARCH AND INTERVENTION

Health, education and gender are important variables in basic research in ageing. Controlling for them often substantially reduces the effects of chronological age (the usual index of ''ageing''). It is possible to contrast the age trends in physiological or psychological performance for subjects suffering from known pathologies with the age trends for subjects free from such pathologies. Rabbitt[9] reports that when adults with diabetes are compared with subjects who do not have diabetes but are comparable in other respects, including intelligence, the diabetics perform less well on measures of information processing. Rabbitt also reports that moderate deafness can have a similar, indirect, deleterious effect on information processing. This supports the use of specific health measures as co-variates in research on ageing.

One of the difficulties in both cross-sectional and longitudinal studies of ageing is that samples of older respondents are biased in at least two ways. First, volunteer respondents tend to be physically, psychologically and socially advantaged, relative to non-volunteers of the same age. Sampling bias is a major obstacle to research in ageing. It restricts our ability to generalize our findings to the wider population. Second, older respondents, even

older volunteers, are more likely than younger respondents to have various physical and psychological impairments that adversely affect their performance: for example, lack of exercise may impair cardiac function; poorer vision or hearing may slow reaction times and increase errors; social isolation may increase anxiety or depression; disuse, as well as irreversible deterioration, may impair performance, as in driving or playing games; training and practice can help compensate for these losses. These and other sampling biases mean that cross-sectional or longitudinal comparisons are likely to be distorted. If we do not have data on relevant background variables, then we cannot take them into account when we try to interpret age-related effects on performance.

A distinction can be drawn between research samples that are actually representative of their age group, and samples of other sorts. People who survive to later ages differ in a number of ways—biologically, psychologically and socially—from non-survivors. Thus, a representative sample drawn from an older population is not directly comparable with a representative sample drawn from a younger population. Matching members of an older sample with members of a younger sample means using samples biased with respect to the parent population. In a longitudinal study, dropouts have the effect of changing the population represented by the remaining sample.

Research samples consist of two main sorts: (a) volunteers recruited by advertising, "snowballing" or other forms of gentle persuasion; and (b) subjects recruited in ways that make it difficult for them not to take part. In the latter sort of recruiting, the benefits of participation are held to be of direct personal benefit, or in the public interest, as with samples based on medical registers. Risch *et al.*[10] report on the difficulties encountered in recruiting "normal" volunteers for psychiatric research. Systematic psychiatric screening, over the telephone, failed to exclude 25% of unsatisfactory volunteers, as judged by subsequent tests. However, in a smaller subsequent study, a warning that reimbursement would be withheld if their toxicology test proved positive was effective. In reply, Halbreich confirms the need for close examination of research volunteers, but raises questions about how to achieve this, and about the ethical issues involved[11]. He also considers that screening normal volunteers should include a family history.

Most psychological studies of ageing appear to assume, rather than test, that their volunteers are "normal", although there may be routine mention of the fact that the respondents are free of obvious physical or mental impairment. The usual assumption is that volunteer samples are biased towards better-than-average health, ability, education and social status. Todd *et al.*[12] describe ways of improving volunteer rates. Bromley (*op. cit.*) describes a number of methodological difficulties encountered in research into normal ageing, including the difficulties associated with sampling and psychological measurement.

The effects of age, cohort and time of measurement are difficult to disentangle. The method of age-matched controls is often used to compare normal with pathological ageing. The problem here, as in selecting a sample of normal respondents, is how to determine which variables need to be controlled. There are numerous biological, psychological, social and environmental factors known or thought to be involved in ageing, and doubtless many unknown factors. The onus is on the investigator to justify the inclusion or exclusion of particular controls, and on the critic to identify other possibilities. Research needs to move beyond superficial and crude controls for gender, socio-economic status and self-reported health. How this move is to be achieved is itself a research issue (*see* e.g. Fox *et al.*[13]). Social groups that have experienced specific long-term life styles, for example in relation to diet, exercise, exposure to toxic substances, can be compared with "normal" social groups in relation to ageing.

Interventions designed to improve the functional capacities of the elderly have had some success but leave some questions unanswered. A sense of control and efficacy appears to be an important and modifiable personality characteristic in later life[14], but intervention raises ethical and management issues. Physical exercise is effective in improving physiological functions even late in life, but prospective studies are needed to exclude the effects of sample bias and lack of control subjects[15]. Rubin *et al.*[16] describe a prospective study of the onset of dementia in apparently normal elderly volunteers.

Training and practice on sensorimotor and cognitive tasks improve the performance of elderly subjects, but improve the performance of younger adults too. The effects may not generalize much beyond the training task or persist long after training is discontinued. The main point, however, is that performance on the first occasion of an unfamiliar task (in a typical laboratory study) is not necessarily indicative of practised performance on a familiar task of the sort encountered in daily life[17,18]. Recently, more interest has been shown in the role of crystallized abilities (acquired mental skills) in adult life[19]. Practice and experience help to explain the maintenance of high levels of performance in many normal old people.

The concept of normal ageing refers not only to humans but also to other animal species, such as flatworms, rats and monkeys. Plants, too, have their characteristic life cycles. Different strains within a species have their characteristic, normal, patterns of ageing. Selective breeding and treatments, such as dietary restriction and brain chemistry, are used to explore the causes of longevity and age-related pathologies.

It is impossible within the scope of a short article to do justice to the numerous and diverse publications on "normal ageing" that a computer-assisted literature search can identify. The concept of "normal ageing" can be used to refer to various phenomena. The key question is, "Normal in respect of what?"

CONCLUSION

Normal ageing can be defined as a cumulative process of adverse changes in physiological, psychological and social functions that, in a general way, characterize average members of successive older cohorts of adults. This process is at present irreversible and to some extent predictable, but it produces a wide range of differences between individuals in age of onset and rate of change. To a limited extent, people can retard and ameliorate these adverse changes.

Normal ageing is a "socially constructed" concept, referring to an accepted range of variation in the health, appearance and performance of adults at different ages. It is also a "scientifically constructed" concept, referring to research findings in gerontology and other disciplines. Gerontologists find the concept of pathological or abnormal ageing useful in identifying exceptions to and deviations from the normal pattern, but the distinction between normal and pathological ageing remains problematical.

Cohort Studies

Patrick Rabbitt

Age and Cognitive Performance Research Centre, University of Manchester, UK

The word "cohort" originally designated a Roman military unit but has now become a technical term in population studies as a collective noun for any peer group, band or sub-set of individuals under investigation. In current usage, a cohort is any group of individuals who are linked in some way. This link may be experience of common life events, such as particular pathologies, or life transitions, such as menopause, or experience of a particular historical event or socio-economic condition. In gerontology the most common defining factor is age group, and this should be assumed unless some other usage is specified. In gerontology, "cohort" has become a more acceptable term to specify chronological age than the often misused "generation", which has an equally precise and different meaning in studies of kinship terminology.

Note that "age group" may be very loosely defined. For example cohort members may have all been born, or died, in the same week, month, year, decade or even century. The defining boundaries of cohorts cause methodological difficulties because the effects of age are confounded with those of birth cohort and period. That is, groups of people born at the same time (birth cohorts) are by definition all of the same age, and have all lived through the same historical period. Groups of the same age (age cohorts) are not necessarily born at the same time, and so may have experienced different historical periods and events such as wars, with attendant differences in social circumstances. Groups of different ages (different age cohorts) also have not shared particular historical events or periods and, to the extent that their experience of a historical event has overlapped, they have been affected by it at different ages.

Cohort analysis is the methodology of designing and analysing studies to make inferences about the behaviour or condition of a particular sub-group without the necessity for studying them again after one or more successive time periods. It is now the most common methodology used to study changes in behaviour or attitudes, biological and cognitive effects of human ageing and social, political and cultural change. Cohort analyses in developmental and ageing studies are distinguished from longitudinal analyses, in which the same birth cohorts are re-examined at intervals over a period of time. A compromise is cross-sequential analyses, in which different age groups and birth cohorts are repeatedly re-examined and compared with themselves and with others at different measurement points.

Unfortunately, although cohort analyses always allow us to identify and study each of these effects, they do not provide any direct way of examining all of them, independently, in a single study. One reason for this is sampling variability. That is, any cohort samples we can obtain and compare are unlikely to be precisely comparable. A related difficulty, which usually guarantees that samples in gerontological comparisons will not be comparable, is sample attrition. As cohorts age, they lose members and so alter in terms of their credibility as representative samples of the populations from which they were initially selected. The most important limitation on cohort analyses is that there is no way to avoid confounding at least two of the three variables in which we are usually interested: age, cohort and period. This imposes very inconvenient restrictions on statistical analysis; for example, in a multivariate regression analysis, all three variables cannot simultaneously be entered as variables in a regression equation. Although many attempts have been made, and much has been written on the subject, there are still no statistical methods that can clearly separate the effects of birth cohort and period from the effects of ageing. Perhaps the most lucid and helpful discussions have been by Costa and McCrae[1] and Palmore[2]. The current consensus is that decisions must rest on scientific judgement as to which two of the three possible effects are likely to be important, so that the third can be omitted. The

Cohort Studies

Patrick Rabbitt

Age and Cognitive Performance Research Centre, University of Manchester, UK

The word "cohort" originally designated a Roman military unit but has now become a technical term in population studies as a collective noun for any peer group, band or sub-set of individuals under investigation. In current usage, a cohort is any group of individuals who are linked in some way. This link may be experience of common life events, such as particular pathologies, or life transitions, such as menopause, or experience of a particular historical event or socio-economic condition. In gerontology the most common defining factor is age group, and this should be assumed unless some other usage is specified. In gerontology, "cohort" has become a more acceptable term to specify chronological age than the often misused "generation", which has an equally precise and different meaning in studies of kinship terminology.

Note that "age group" may be very loosely defined. For example cohort members may have all been born, or died, in the same week, month, year, decade or even century. The defining boundaries of cohorts cause methodological difficulties because the effects of age are confounded with those of birth cohort and period. That is, groups of people born at the same time (birth cohorts) are by definition all of the same age, and have all lived through the same historical period. Groups of the same age (age cohorts) are not necessarily born at the same time, and so may have experienced different historical periods and events such as wars, with attendant differences in social circumstances. Groups of different ages (different age cohorts) also have not shared particular historical events or periods and, to the extent that their experience of a historical event has overlapped, they have been affected by it at different ages.

Cohort analysis is the methodology of designing and analysing studies to make inferences about the behaviour or condition of a particular sub-group without the necessity for studying them again after one or more successive time periods. It is now the most common methodology used to study changes in behaviour or attitudes, biological and cognitive effects of human ageing and social, political and cultural change. Cohort analyses in developmental and ageing studies are distinguished from longitudinal analyses, in which the same birth cohorts are re-examined at intervals over a period of time. A compromise is cross-sequential analyses, in which different age groups and birth cohorts are repeatedly re-examined and compared with themselves and with others at different measurement points.

Unfortunately, although cohort analyses always allow us to identify and study each of these effects, they do not provide any direct way of examining all of them, independently, in a single study. One reason for this is sampling variability. That is, any cohort samples we can obtain and compare are unlikely to be precisely comparable. A related difficulty, which usually guarantees that samples in gerontological comparisons will not be comparable, is sample attrition. As cohorts age, they lose members and so alter in terms of their credibility as representative samples of the populations from which they were initially selected. The most important limitation on cohort analyses is that there is no way to avoid confounding at least two of the three variables in which we are usually interested: age, cohort and period. This imposes very inconvenient restrictions on statistical analysis; for example, in a multivariate regression analysis, all three variables cannot simultaneously be entered as variables in a regression equation. Although many attempts have been made, and much has been written on the subject, there are still no statistical methods that can clearly separate the effects of birth cohort and period from the effects of ageing. Perhaps the most lucid and helpful discussions have been by Costa and McCrae[1] and Palmore[2]. The current consensus is that decisions must rest on scientific judgement as to which two of the three possible effects are likely to be important, so that the third can be omitted. The

obligation to carry out exploratory data analyses to ensure that the effect that is to be neglected is in fact, statistically unimportant, should not need emphasis.

The inevitable confound between age, cohort and period effects is awkward because it means that we cannot use this most economical of all research strategies to solve all of the many problems connected with ageing. However, bearing their overriding limitation in mind, it must be stressed that cohort analyses are not merely an economical, but methodologically flawed, substitute for laborious longitudinal studies. They rather provide a means by which we can answer classes of questions that cannot be approached in any other way. The fact that the cohorts need not contain the same individuals is a statistical advantage as well as logistical convenience. For example, it can be very useful to sample quite different populations of the same birth cohort at different times in their lives so as to make an intracohort trend study. There are also unique advantages in comparing *n* quite different age samples of a population recruited at successive periods of time. This allows us to draw up what has become known as a "standard cohort table", in which the different age cohorts are ordered in rows, and the successive years in which these different age groups were sampled are ordered in columns. This allows us, at least, a rapid and convenient way to carry out exploratory analyses of our data. We can pick out intracohort trends, which become apparent by scanning down the diagonals; that is, we can see how members of a particular age group (whether represented by the same individuals followed over time, or by quite different samples) are affected by both the passage of time (and so, among other factors, by their own biological ageing) and also by changes in the social, economic or epidemiological contexts in which they were studied. Within each of these sampling periods we can compare age cohort differences by scanning down the columns. Finally, by scanning along the rows, we can examine period effects which occur as one age cohort replaces another.

No single technique of comparison, whether cohort analysis, longitudinal analysis or even cross-sequential analysis, can provide a universal methodological panacea. Rather, each can solve problems that the others cannot approach, and none save us the effort of carefully thinking through the questions that we wish to ask of our data, and intelligently considering the implications of the comparisons we must make to answer them. To study the effect of ageing we must simultaneously acquire both cross-sectional and multiple longitudinal data and interpret them as sensibly as we can.

Chronological and Functional Ageing

Jack M. Guralnik and David Melzer*

National Institute on Aging, National Institutes of Health, Bethesda, MD, USA,
**Department of Community Medicine, Institute of Public Health, University of Cambridge, UK*

Chronological age is the major descriptor by which aging is defined. In an effort to characterize the dynamics and variability of the aging process, recent approaches have used measures of functional aging to reflect the observation that individuals may function at a level above or below that expected for their chronological age. The relationship between chronological and functional age has implications for major questions of aging research and public policy. Do humans have a fixed lifespan? How can we maximize functioning for any given age? How is functional aging associated with vulnerability to disease? Should retirement be mandatory at a certain chronological age or should functional age play a role in this decision?

CHRONOLOGICAL VS. FUNCTIONAL AGING

Chronological age is defined as time since birth; its effect is analyzed in virtually all health studies and indeed in nearly all areas of human research. Although chronological aging is strongly associated with mortality and nearly all diseases, it should not be viewed as an etiologic factor. It is rather a proxy for numerous factors that change or accumulate over time, such as cumulative exposure to toxins and trauma, changes in hormone levels, immunological defenses and genetic repair mechanisms. A great deal of work has gone into identifying factors that explain the relationship between chronological age and susceptibility to disease and dysfunction, but much of this relationship remains unexplained. Identifying chronological age as a risk factor may be of little value, not because age is not strongly related to disease incidence but because an intervention to change one's age is not available. For developing prevention strategies, however, understanding an age association may be important, such as the finding that bone loss accelerates for 10–15 years after menopause, slows for a number of years, and again accelerates after age 75.

A number of different concepts, including functional age, biological age and biomarkers of aging, have been developed based on the observation that physiological measures and functional performance show a range of values in a population of a given chronological age. Functional age is a concept that rests on the premise that a measure other than chronological age could better reflect one's position in the aging process. Although biological and functional age have been defined differently, they are frequently used interchangeably. In contrast to chronological aging, which occurs at a universal fixed rate, functional aging has been termed "non-chronological" because its rate may accelerate or decelerate and, in fact, functional age may be greater or less than one's chronological age.

The concept of biomarkers of aging is particularly appealing because it implies that there are biological measures that reflect the rate of aging and that successful interventions on the aging process would have an effect on these markers. It is unclear at this time whether there is an underlying biological state of aging that can be summed up as a single number that indicates how far along in the aging process the individual has progressed. It has been argued that aging is a complex, uncoordinated phenomenon that can not be summed up in such a way[1]. Others believe that, although a well-validated set of biomarkers does not currently exist, there may be techniques developed that can work well as general indicators of biological age[2]. The requirements of a biomarker are not that it simply be different in persons or animals of different ages but that, in a group of subjects of the same age, it has a distribution of values that relates to other age-sensitive traits, such as longevity[2].

Much of the work done on functional aging has focused on physiological changes that are part of normal human aging. Another aspect of functional aging, which may be termed "functional health status", assesses functioning at the level of the whole older person, describing how that person functions in daily life. Functional health status has been found to be related to chronological age, disease and a variety of other modifying factors. Measures of functional health status have also proved valuable for clinical and health services research[3]. The USA's national goal to increase the span of disability-free life exemplifies the high level of interest in the measurement of functional health in recent years[4].

FUNCTION VS. DISEASE IN CHARACTERIZING OLDER PERSONS AND OLDER POPULATIONS

Understanding the functional aspects of aging has been an important part of geriatric medicine for several decades. In the medical model of disease, the clinician gathers symptoms and signs, makes a diagnosis, and bases the therapeutic approach on this diagnosis. Complementing this disease-orientated approach, functional assessment provides an understanding of the impact and consequences of the older person's disease or diseases, giving information on level of independence and prognosis, as well as health care, rehabilitation and social needs. As aging research has increased in recent years, the functional approach has played an important role in its agenda.

Although normal physiological changes with aging may have an impact on the older person, the far greater functional impact comes from the effects of disease. A framework that represents the

relationship between disease and disability is therefore valuable in developing the concept of functional aging. The World Health Organization has proposed a theoretical pathway progressing from disease to impairment to disability to handicap[5]. An alternative pathway, proposed by Nagi[6] and utilized by the US Institute of Medicine[7], progresses from diseases and conditions to impairment to functional limitation to disability. An effort to operationalize this latter pathway defines ‘‘impairment’’ as dysfunction and structural abnormalities in specific body systems, ‘‘functional limitation’’ as restriction in basic physical and mental actions such as ambulating, grasping and stepping up, and ‘‘disability’’ as difficulty in doing activities in daily life such as personal care, household management, job and hobbies[8]. Although these pathways have remained essentially theoretical, increasing efforts are now under way to use empirical data to document important steps along the pathway[9].

Disease severity and the co-occurrence of multiple diseases (co-morbidity) play an important role in the process of disablement. In a study using data representative of the older US population, it was found that the prevalence of disability increased with increasing number of chronic conditions, after adjusting for age and sex[10]. The synergistic effect of specific pairs of diseases on disability has also been demonstrated. It is also clear that intervening behavioral, environmental and social factors play an important part in modifying the pathway along its entire course and need to be understood more fully[11,12].

DOMAINS OF FUNCTIONING AND MEASURES OF POPULATION DISABILITY

Functional aging is a multidimensional concept for which several domains must be considered to adequately characterize the total older person. Domains central to aging include physical, cognitive, psychological, sensory and social functioning. In the older population it is of value to separate the cognitive and psychological domains, although at times it may be difficult to ascertain whether cognitive impairment is related to a dementing disease or depression. The importance of sensory impairments in limiting overall functioning is receiving increasing attention in ongoing gerontological research. Social functioning, critically important in the lives of older persons, reflects the impact of the other domains on interactions with family, friends and the community.

Physical functioning, to be the focus of the remainder of this chapter, has traditionally been assessed through self-report of the ability to perform specific tasks, including self-care activities such as bathing and dressing (activities of daily living) and activities necessary to maintain independence in the community, such as shopping and food preparation (instrumental activities of daily living)[13–15]. In cases where individuals have severe physical or cognitive impairment, proxies have been successfully employed to assess functional status, although proxies who have limited contact with the subject tend to provide less valid information[16]. Recently, performance measures of functioning, in which the individual is asked to actually perform standardized tasks, have been employed[17].

A number of national surveys have estimated the prevalence of functional disability in the US population[18]. The prevalence of disability in activities of daily living (ADLs) in the non-institutionalized population rises steeply with increasing age and is slightly higher for women compared with men at the older ages (Figure 13.1)[19]. These rates do not reflect that portion of the population residing in nursing homes, where it is estimated that over 90% of residents require help with ADLs[20]. It is important to keep in mind that, although chronological age is strongly related to disability prevalence, many other factors, such as socio-economic status, have large impacts on disability that are independent of age[12].

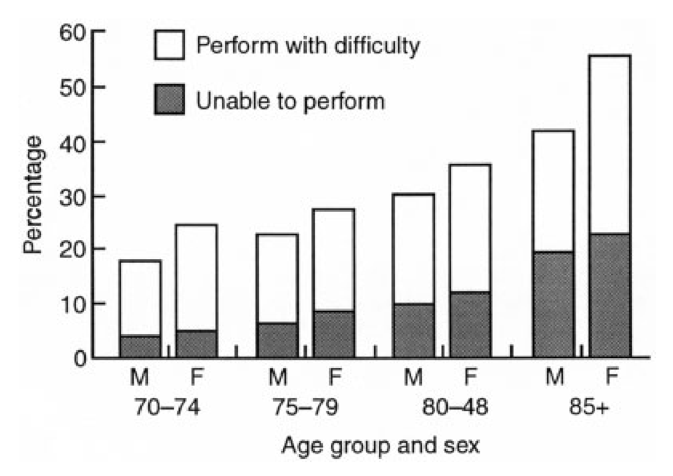

Figure 13.1. Percentage of persons have difficulty or being unable to perform one or more activities of daily living by age and sex, USA, 1995. Activities of daily living include: bathing or showering, dressing, using the toilet, getting in and out of bed or chairs, and eating, walking and getting outside. Source of data: Second Supplement on Aging to the 1995 National Health Interview Survey

COMPRESSION OF MORBIDITY AND THE MEASUREMENT OF ACTIVE LIFE EXPECTANCY

An important issue related to functional aging is the relationship between length of life and the amount of time spent in the disabled state. Life expectancy has increased very substantially in this century. A consequence of this, which is just beginning to be appreciated, however, is that escaping death during the early years from infectious diseases and other causes may mean that many more people survive to ages where they suffer from chronic diseases, which can lead to long-term disability and loss of independence. A major goal of gerontology is to increase longevity without increasing the number of years spent in the disabled or dependent state. Although the recent increase in longevity is well documented, it is not now clear whether these added years of life have been accompanied by years of health and vigor or disease and disability. This question is of particular concern in the coming century, when it is projected that there will be continued increases in life expectancy and unprecedented numbers of old and very old persons. The theory of compression of morbidity predicts a future decrease in the number of years with severe disease and disability[21].

An important tool for evaluating compression of morbidity is what has been termed ‘‘active life expectancy’’ or ‘‘disability-free life expectancy’’[22]. Active life expectancy is defined as the average number of years an individual at a given age will survive and remain in the active, or non-disabled, state. Most analyses of active life expectancy have employed the ADLs to define disability, with active life expectancy calculated using life table techniques which consider transitions from the active, non-disabled state to both death and disability. The original analysis of active life expectancy considered the transitions to both death and disability as irreversible[22].

However, recent longitudinal studies of aging populations have revealed that a substantial proportion of disabled persons make the transition back to the non-disabled state. Methods to calculate active life expectancy based on these kinds of changes, using multistate life tables, have been developed[23].

The relationship over time between life expectancy and active life expectancy can be used to assess the occurrence of a compression of morbidity. Three possible scenarios for population morbidity in women are illustrated schematically in Figure

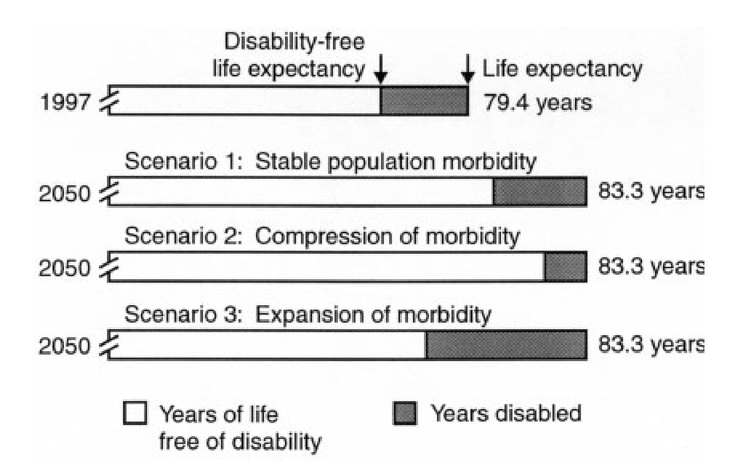

Figure 13.2. Scenarios for change in average burden of population disability level, 1997–2050. Compression of morbidity and alternatives

13.2. The total length of the bars in this figure represent life expectancy observed for 1997 and projected by the Census Bureau for 2050. The length of the unshaded segments of the bars represents active or disability-free life expectancy, and the shaded areas of the bars represent the average number of years in the disabled state. In scenario 1, the onset of disability has been postponed the same number of years as life expectancy has increased, and the number of years spent in the disabled state is unchanged from 1997. In scenario 2, there has been a compression of morbidity. Finally, in scenario 3, although disability-free life expectancy in 2050 has increased compared with 1997, it has not kept pace with increases in life expectancy and there is an expansion of population morbidity.

A vigorous debate over the prospects for a compression of morbidity began with a landmark paper by Fries, in which he made the claim that the compression of morbidity was inevitable in the coming years[21]. He argued that in all species the maximum lifespan is fixed, that human beings are quickly approaching this limit, and that with a stable life expectancy any postponement of disease and disability would result in a compression of morbidity. Although this logic is correct, others have pointed out that life expectancy is probably not going to reach its maximum level for at least the next half century and we must consider that any of the alternative scenarios depicted in Figure 13.2 are possible in the face of increasing life expectancy.

Repeat estimation of active and disabled life expectancy over time using identical techniques in the same target population would allow for a direct assessment of compression of morbidity, but these data are not available. However, disability prevalence, which is not equivalent to disabled life expectancy but reflects a cross-sectional picture of the proportion of the population that is disabled, can be estimated, and a great deal of attention has been focused on longitudinal trends in disability. In the 1970s there was some evidence of a rising prevalence of disability, but in the 1980s rates appear to have declined[24–26].

For example, Manton *et al.*[24,27] have reported an average annual adjusted decline of 1.1% in the prevalence of a composite measure of severe disability in the population aged 65 and over, from the US National Long Term Care Survey for the period 1982–1994. Freedman and Martin[26] reported similar declines in a more specific measure of difficulty in walking or use of mobility aids from the Survey of Income and Program Participation: for example, the prevalence of disability defined by this criterion declined during the 10 year study period from 30.6% to 27.2% at age 65–79 and at age 80 and over from 44.0% to 40.9%. Although there is a scarcity of longitudinal data from other countries, similar findings have been reported[28] with only a few exceptions where rates have probably been stable.

Possible causes of these declines in disability prevalence include environmental changes making daily tasks easier[8], more intensive use of assistive devices[29] and other social changes, including attitudes to being active in old age. In addition, the proportion of older people who have little education (a potent risk factor for disability) has declined[26,30]. There is also evidence of declining prevalence of some medical conditions in old age, especially cardiovascular disease. Health risk avoidance and improved diagnostic and therapeutic techniques will also have contributed.

The future burden of morbidity and disability in the older population is of great concern to those involved in planning, financing and delivering health care and social services. If current rates of disabling diseases such as Alzheimer's disease and hip fracture remain unchanged, the numbers of older people with these diseases will increase substantially in the next century[31]. Gaining an understanding of factors that have an impact on functional aging is critical if we are to reduce the burden of disability and achieve a compression of morbidity. Ultimately, effective interventions must be developed to prevent the onset and mitigate the consequences of diseases that lead to much of the disability in late life.

Health Expectancy: Monitoring Changes in Population Health

Carol Jagger

University of Leicester, UK

The increasing life expectancies experienced by many countries over the last decade have made the debate about the quality and quantity of years lived at older ages particularly relevant for conditions such as dementia, where the prevalence rises steeply with age. Health expectancies were developed to address the question of whether or not longer life is accompanied with a decrease in the quality of life, and they extend the concept of life expectancy to morbidity and disability by providing a means of dividing life expectancy into life spent in various states of good and bad health. Being independent of the size of populations and of their age structure, health expectancies thus allow direct comparison of the different groups that constitute populations: sexes, socioprofessional categories, regions.

As health expectancy combines a life expectancy with a health measure, there are as many possible health expectancies as health measures; for example, disability-free life expectancy, active life expectancy (based on independence in Activities of Daily Living), healthy life expectancy (based on good perceived health) or dementia-free life expectancy. Bone *et al*.[1] reports values for these and other health expectancies for the UK from two longitudinal studies of older people (the Melton Mowbray Ageing Project and the Nottingham Longitudinal Study of Activity and Aging) and from national cross-sectional studies. Dementia-free life expectancy at age 65 years has now been calculated for five countries: France, UK, Belgium, Eire and The Netherlands[2]. Despite difference in life expectancies between countries (ranging for men from 13.5 years in Eire to 15.4 years in France and for women from 16.9 years in Eire to 19.7 years in France), women can expect to live between one and two years and men between 0.5 and 0.7 years of their remaining life with dementia.

Today, estimates of health expectancy (generally disability-free life expectancy) are available for 49 countries[3], although comparisons across time and between countries are still problematic due to the lack of harmonisation of measures and study designs. REVES (Réseau Espérance de Vie en Santé: the International Research Network on Health Expectancy) is an international organization of researchers, clinicians and health planners addressing these issues as well as developing and recommending methods of calculation and furthering the use of health expectancy as a tool for health planning.

Life Satisfaction

Linda K. George
Duke University, Durham, NC, USA

Maddox and Wiley[1] suggest that the ''relationship between aging and successful adaptation (variously 'morale' or 'life satisfaction' or 'well-being') is perhaps the most persistently investigated issue in the social scientific study of aging''. This statement, made a quarter century ago, remains true today. Life satisfaction is variously viewed as a prime indicator of overall life quality, a testimony to the importance of social structure and location for person well-being and one component of ''positive mental health''[2]. Life satisfaction research also has helped to balance the vastly overstated crisis orientation that characterized aging research in the past[3]. This chapter examines several facets of life satisfaction in later life: definitional issues, the epidemiology of life satisfaction in later life, major determinants of life satisfaction, mechanisms that may account for age differences in life satisfaction, and some final comments about future directions for life satisfaction research.

WHAT IS LIFE SATISFACTION?

Life satisfaction is most frequently defined as a global assessment of life quality, derived from comparison of one's aspirations to the actual conditions of life[4,5]. Because ''life as a whole'' or ''life in general'' is assessed, a long-range time perspective and non-specific life conditions are implied. Life satisfaction is one of a number of concepts that can be subsumed under the more general rubric of subjective well-being. Other indicators of subjective well-being are happiness and mood. Two primary factors underlie the distinctions among these concepts: the ratio of cognitive to affective judgment involved and time frame. Although all subjective well-being measures involve evaluation along a good–bad continuum, life satisfaction is primarily a cognitive assessment of the discrepancy between aspirations and achievements. In contrast, happiness and mood are primarily emotional judgments. In addition, happiness and mood are quite transitory, whereas life satisfaction tends to be stable (although it is sensitive to major events and changes in life conditions). Because it is a more cognitive, stable phenomenon, life satisfaction has been a more attractive candidate for the study of quality of life during old age. Researchers have understandably been more interested in relatively stable judgments of life quality than in indicators that fluctuate widely over brief periods of time.

How life satisfaction is defined has direct implications for methods that can be used to alleviate dissatisfaction. Dissatisfaction represents a significant discrepancy between one's desired life conditions and one's actual life conditions. Consequently, the two major ways to reduce dissatisfaction are either to engage in goal-directed behavior that brings achievements closer to aspirations or to reduce aspirations so that they more closely match the actual conditions of life. As we will see, older adults are especially adept at using the latter strategy to sustain high levels of life satisfaction.

THE EPIDEMIOLOGY OF LIFE SATISFACTION

How satisfied are older adults with their lives? This question has been investigated for 40 years, with consistent results. Studies of samples of both older adults and of adults of all ages consistently document that the vast majority (i.e. typically 85%) are satisfied with their lives[4–7]. Between the 1960s and the 1980s, the life satisfaction of older Americans increased slightly relative to that of the non-elderly[8]. In studies conducted during the 1960s and earlier, older adults were somewhat less satisfied with their lives, on average, than their younger peers. By the mid-1970s, however, this pattern had reversed and has remained stable for more than two decades.

DETERMINANTS OF LIFE SATISFACTION

What are the major determinants of life satisfaction during old age? Research suggests that they fall into two primary categories: (a) objective life circumstances and (b) personality traits and other psychological characteristics.

Objective Life Circumstances

For all adults, regardless of age, the major determinants of life satisfaction include attachments to social structure (especially education, occupation and marital status), personal resources (including health and income), involvement in and support from primary groups (family and friends) and participation in meaningful social and leisure activities[4,5,9–11]. Recent evidence indicates that religious participation also is a robust predictor of life satisfaction[12,13].

Although the same basic set of objective life circumstances underlie life satisfaction for all adults, the meaning and salience of those determinants may vary across ages or stages of the life course. What is highly important for a sense of well-being at one life stage may be less relevant at another. For example, George, Okun, and Landerman[9] found that: (a) marital status is less important for a sense of well-being among young adults than among middle-aged and older adults; (b) income is most important for middle-aged adults and least important for young adults, and intermediate for older adults; (c) health is much more

important for older adults than for middle-aged and younger adults; and (d) social relationships are more important for younger and older adults than for the middle-age[9]. The degree to which the determinants of life satisfaction differ across age groups merits further investigation.

Despite evidence that life satisfaction is strongly related to objective life conditions, levels of life satisfaction typically remain stable, even in the face of substantial change in its documented predictors. It is true that significant social losses, especially widowhood and the onset of disability, are associated with decreases in life satisfaction. More surprising, however, is the fact that levels of life satisfaction remain stable in the face of other major changes in life circumstances. For example, although retirement typically results in a 50% reduction in income, there is no evidence that retirement and its accompanying reduced income lessens life satisfaction[14]. Indeed, life satisfaction can be sustained in the midst of potentially devastating chronic stress, as documented in a study of more than 500 family caregivers of demented older adults. Among this sample of caregivers, the average level of psychiatric symptoms was eight times greater than that for random community samples, more than one-third of the caregivers reported using psychotropic drugs, and nearly one-quarter used alcohol on a regular basis to cope. Nonetheless, fully 80% of these caregivers reported that they were satisfied or very satisfied with their lives—a figure only 5% lower than that typically reported in random samples of American adults[15].

These findings testify to the distinctive character of life satisfaction—by definition, life satisfaction refers to subjective perceptions that go beyond the effects of objective life conditions. We need to know more about the cognitive and emotional processes that lead some older people who appear well off in terms of their objective life circumstances to nonetheless find life dissatisfying and burdensome. Similarly, we need to know why it is that many older adults who are less well off than their younger peers—and, indeed, than they were at younger ages—nonetheless find life meaningful and satisfying[16].

Psychological Characteristics

One reason that life satisfaction may be overwhelmingly stable and only partially reflect objective life conditions may be that it reflects, in part, psychological characteristics. Several relatively stable personality traits are significant predictors of life satisfaction: neuroticism, extroversion vs. introversion, and openness to new experience or cognitive flexibility[17–19]. Other social psychological characteristics are related to subjective well-being as well. For example, interpersonal trust is associated with higher life satisfaction[20]. Personal coping strategies also have implications for life satisfaction. Selective optimization with compensation is a coping strategy in which older adults who face limitations due to health problems or diminishing social networks choose to increase their commitments to specific life domains in order to compensate for the inability to invest in other life domains. This strategy for coping with age-related decrements is associated with higher levels of life satisfaction than other coping strategies during late life[21].

EXPLANATORY MECHANISMS

Before examining potential explanatory mechanisms that underlie subjective perceptions of life quality, another age difference in reports of life satisfaction must be noted. There is considerable evidence that older adults are satisfied with life conditions that are objectively worse than those needed to produce perceptions of equivalent life quality among middle-aged and younger adults[8,9]. For example, some economists have observed that older persons often express satisfaction with levels of income that are substantially below those required for minimally adequate food, shelter and medical care[22,23]. Three types of explanatory mechanisms have been suggested as possible explanations for this pattern.

One possible explanation is aspiration theory which, as previously described, has been the basis of most conceptualizations of life satisfaction. From this perspective, some scholars argue that older adults are masters of the art of lowering aspirations to meet realities. A related hypothesis suggests that, because measures of life satisfaction focus on the long term, older persons often view current deprivations as paling in comparison to the dominant patterns of their lives[24,25]. Although aspiration theory can describe plausible ways in which older adults can make peace with less than optimal life conditions, it cannot explain why older adults are willing to lower their aspirations substantially more than younger and middle-aged adults.

Second, other authors have suggested that younger adults use aspiration–achievement comparisons in making judgments about life satisfaction, whereas older persons assess the quality of their lives in terms of perceived equity. Research by Carp and Carp[26] suggests that young and middle-aged adults are satisfied when their achievements closely match their aspirations. In contrast, older adults are satisfied with life when they perceive their life conditions as fair and just (i.e. as matching what they ''deserve'').

Third, and similar to equity theory, is the theory of relative deprivation, which posits that people will feel deprived only when they see themselves as worse off than others to whom they can appropriately compare themselves[27]. There is strong evidence that most older people see themselves as better off than the ''average older person''. According to relative deprivation theory, this kind of social comparison will result in high satisfaction. Equity theory and relative deprivation theory share the same problem noted above for aspiration theory. Although each can provide a plausible explanation for why older adults are often satisfied with less than their younger peers, neither explains why many older adults use these strategies to sustain high life satisfaction in the absence of optimal life conditions and most young and middle-aged adults do not.

FINAL THOUGHTS

Much has been learned from a half century of research on life satisfaction. We know and can rejoice in the fact that most older adults find life to be highly satisfying—as do most middle-aged and younger adults. We know that there are robust relationships between objective life conditions and perceptions of life quality. To the extent that this is true, high levels of life satisfaction among older adults confirm that older persons in modern societies share with their younger peers the material and social resources that make life enjoyable and satisfying. We also know, however, that older persons often express satisfaction with levels of resources that are below those necessary for quality of life. In this sense, we cannot deny the possibility that older people are not as well off in important ways as their subjective perceptions would suggest. This possibility—this nagging doubt as to the meaning of older persons' reports of life satisfaction—raises two additional questions that merit increased scrutiny.

First, from a policy perspective, it is prudent to examine the objective life conditions of older adults' lives as well as their ratings of life quality. We do not want, for example, to set standards for the economic resources needed to sustain quality of life on the basis of the thresholds that older people report if they, in fact, report levels that are below those needed to sustain adequate food, shelter and medical care. Similarly, we do not want to ignore the legitimate health and mental health needs of family caregivers of impaired older adults based only on the fact

that most caregivers report that their lives are satisfying. A related implication for policy analysis is the utility of life satisfaction measures for assessing the effects of intervention. Given the stability of life satisfaction measures in the face of all but the most major changes in life circumstances, it is probably unwise to evaluate the utility of an intervention on the basis of changes in life satisfaction. Such measures may be so insensitive that meaningful changes in life circumstances would be missed if life satisfaction were the only outcome examined. Moreover, most interventions need not improve life satisfaction to be demonstrably beneficial. For example, interventions that prevent illness or help to alleviate the functional consequences of illness need not improve life satisfaction to be beneficial. It is enough that they make a demonstrable difference in the incidence or functional consequences of disease.

Second, although it may be problematic for policy purposes that perceptions of life quality often stray rather far from objective life conditions, there is something admirable in the fact that most older people find life satisfying despite deprivations in the material and social resources so highly valued in modern societies. We need to investigate the foundations of this phenomenon. Increased understanding of this perplexing facet of life satisfaction is most likely to occur if subjective experience more broadly becomes the focus of investigation. In particular, increased attention should be devoted to studying the life of the self in old age and the sources of meaning that older adults attach to various life domains.

The 15% of the older population who are not able to sustain a sense of well-being also should not be ignored. Although we know that these older adults fare less well than their age peers on measures of income, health, social bonds and leisure participation, we know little else about them. We do not know, for example, whether their dissatisfaction in old age is a life-long pattern or is a response to age-related losses. Given the stability of life satisfaction measures, we also know little about how to facilitate higher levels of satisfaction among these individuals. Modern societies do quite well at providing the social and economic conditions that allow most older adults to find life satisfying. But we still do not know much about how to change life satisfaction. Such knowledge is of high priority, both for the practical purposes of promoting life quality and for gaining a better understanding of its dynamics.

Finally, we must remember that there is important information yet to be learned about life satisfaction. Life satisfaction is not the key barometer of successful aging (as, unfortunately, some of its advocates have implied). But it is important. It is important because it reminds the scientific community that we should be interested in enhancement as well as rehabilitation, in promoting the good life as well as intervening to alleviate bad times. Life satisfaction matters because it demonstrates that social, economic and psychological factors are as important in understanding life's triumphs as its tragedies. Life satisfaction is important because it reminds us to strive for health as well as the absence of disease and to invest in mental health as well as the amelioration of mental illness.

The Normal Aged among Community-dwelling Elders in the UK

Christina Victor

Department of Public Health Sciences, St George's Hospital Medical School, London, UK

INTRODUCTION

In 1851 there were approximately 1 million people in Britain aged 65 and over, representing 5% of the total population, compared with 9 million or approximately 16% in 1991 and a projected 11 955 000 in 2021[1]. The reasons for this demographic transformation, which is not unique to the UK, have been discussed elsewhere in this book. One very visible manifestation of this change in the structure of our population is the increase in the number of centenarians. At the turn of the century, there were only a handful of British centenarian subjects, 200 at most[2]. As we enter the next millennium there are approximately 6000 Britons aged 100 or more[2]. One feature of population ageing in the next millennium will be the "ageing" of the ethnic minority populations of Britain, which will pose a new set of challenges[3]. Instead of this demographic trend being welcomed as a triumph for public health, population ageing is portrayed as an impending social disaster. Increasingly over the course of this century, old age has been depicted as a "social problem", especially with regard to the health and financial consequences of an ageing population[4,5]. Consequently, research in social gerontology has been dominated by the policy-makers' agenda, which perceived old age as a social problem. The bulk of research has, therefore, concentrated upon defining and enumerating the social problem and pathological aspects of ageing, rather than on enhancing our understanding of "normal" ageing[6]. This is particularly true in the area of health and medicine where, until recently, dementia was seen as a part of "normal" ageing and where there are major debates as to how we are to afford to pay for the health care of older people. It is only recently that researchers have extended the horizons of their research to include research into the non-pathological aspects of later life.

One reason why the prospect of an ageing population is perceived so negatively is because of the prevailing images of the characteristics of the old age and older people generally. These images, beliefs and stereotypes are then transferred to the whole population. Stereotypes about the nature and characteristics of old age and older people abound and reflect a societal ideology which is predominantly youth-centred. To paraphrase the most common beliefs about older age, older people are seen as socially isolated, abandoned by their families, ridden with ill-health and disease (indeed, old age is synonymous with ill-health and disease), consuming excessive amounts of societies' health and social care resources and not contributing in any way to society (i.e. being parasitic upon the young, vigorous working population). Older people are further viewed as being inflexible, lacking vigour, being incapable of learning and shunning innovation and new technology. By inference, an ageing population is seen as being stagnant, uncompetitive and unable to compete or innovate as well as "young" populations. In the rest of this chapter we consider how valid some of these stereotypical images are.

THE LIVING ARRANGEMENTS OF OLDER PEOPLE

One very prevalent image of later life is that of living in institutional care. It is popularly believed that most older people live "in care" (either in a residential or nursing home). Although only approximately 5% of those aged 65+ live in some form of institutional care, this percentage is widely perceived as being much greater[7]. Even for the "oldest old", those aged 90 or more, approximately half are still living in their own homes in the community[8]. For those older people living in the community, another common image is the association of later life with residence in "special" types of housing, such as sheltered housing. Again this is a type of accommodation characteristic of only a minority of older people, with approximately 10% of those aged 75 and over living in such types of housing[1]. Hence, we can conclude that the majority of older people, some 70–99% (depending upon age) live in the community and in "ordinary" housing in the same way as the rest of the population. Home ownership is the main form of tenure, with 68% of those aged 65 and over owning their own homes in 1996/97[1]. A further 27% lived in accommodation rented from the public sector[1]. However across the tenure groups, older people are more likely than other age groups to live in older housing, which typically is in poorer repair, lacking in standard amenities and adequate heating. This is especially true for the minority of older people, approximately 10%, who live in private rented accommodation.

Within Britain, the post-war period has witnessed profound and far-reaching changes in patterns of family formation and household structure. In Britain in 1999, approximately 38% of those aged 65+ lived alone compared with about 10% in 1945[9]. Over the same period, the percentage of older people living with their spouse only has increased to about 50% from 30%. There

are, of course, important variations between men and women in terms of living arrangements. At all ages, because of the differential age at marriage between men and women and higher male mortality rates, there are more women living alone than men. For example, 26% of men aged 85 and over live alone, compared with 49% of women of the same age[1]. Simultaneously, the percentage of older people living in larger households of two (or more) generations has decreased to about 10% of those aged 65 and over. Superficially the increase in "solo living" and decrease in the multi-generational household is often interpreted as evidence of the "rejection" of older people by their children and other relatives. However, these changes in household composition are, in fact, the result of much wider social changes, including the trend for younger people to establish independent households on or before marriage, geographical mobility, smaller families and increased rates of marriage combined with the improved financial resources available to older people, which allow them to express a widespread desire for independent living in later life.

SOCIAL NETWORKS AND SOCIAL CONTACT

Older people are often portrayed as a socially isolated group who are neglected by both their families and the wider social world. A key factor in considering the social networks of older people is the availability of kin and especially the marital relationship. The cohort of older women who never married, the post-World War I "spinster generation", has almost died out. Indeed, the percentage of single (never married) women has deceased from 16% of those over 80 in 1972 to 10% in 1999[1]. For the current population of older people, approximately 7% have never married[1]. The percentage of older people who are married varies markedly between men and women. Up to the age of 85 and over, the majority of men are married compared with 16% of women. For women the majority of those aged over 70 are widowed. Hence, for women the loss of a spouse can vastly restrict their social networks. However, the vast majority (97%) report the existence of close relatives and the presence of a close confiding relationship[10,11]. Generally the pattern of contact between older people and their relatives and friends contradicts the image of neglect, as at least 75% of older people report weekly contact with relatives/friends[1]. Amongst older women especially, friendship levels are both extensive and important[12,13]. Furthermore, research has consistently demonstrated that only a minority of older people report that they feel lonely, although this percentage does increase with age and disability[14] but is not synonymous with living alone[14]. Older people are also engaged members of society, as measured by their participation in social, cultural and voluntary activities[1].

HEALTH STATUS

Perhaps the most potent stereotype of all concerning later life relates to the perceived universal prevalence of illness, disability and infirmity. It is widely assumed that chronic ill-health, incontinence and mental impairment is the norm amongst the older age groups. How accurate is this image?

There are a variety of different ways of describing the health status of any given population. One widely used index of health status is mortality data. In Britain, mortality rates show a J-shaped distribution, being high in the first year of life and then decreasing in childhood. Rates then increase with age, so that 75% of deaths in England and Wales of the approximately 500,000 deaths annually were accounted for by those aged 65+[15]. In both Britain and the USA there have been significant reductions in later life mortality rates over the past four decades, which have contributed to increased life expectancy in later life. In 1980, men and women aged 85 could expect to live, on average, for another 4.3 and 5.8 years, respectively. By 1994 this had increased to 5.3 years and 6.8 years because of decreases in later life mortality rates[1].

Whilst mortality data are useful, they tell us nothing about the health status of those who have not died. However, morbidity data are difficult to collect on a routine basis. One important British source of such data is the General Household Survey, which provides data about the prevalence of acute and chronic health problems amongst the general population of older people resident in the community. For acute self-limiting conditions prevalence rates increase only slightly with age, from 10% for those aged 16–44 to 20% at age 85+[15]. Chronic health problems, as measured by long-standing limiting illness, show a much stronger age gradient, increasing from 12% of those aged 16–44 to 53% at age 80+–91[15]. Although there are variations in disability prevalence estimates between studies, it is clear that chronic health problems are not universal in later life. Again, the last decade has, in Britain, been characterized by an increase in the number of years an older person can expect to live "free from disability"[1]. Hence, the increase in life expectancy has not been accompanied by an increase in the amount of disability experienced by the "average" older person.

Within the elderly population there are important differences in health status, which largely mirror those of the population of working age[15]. For chronic ill-health, women show higher prevalence rates than men of the same age. For example, at 80 and over approximately 48% of men and 55% of women report that they have a long-standing limiting illness[1]. Furthermore, there are significant differences in health status between the social classes. At all ages older people from professional and managerial occupations show rates of chronic ill-health which are significantly lower than their counterparts from the manual occupation groups[16]. Expectation of life at age 65 for men also varies from 16.8 years for those from social class 1 (professional occupations) to 12.6 years for those from unskilled occupations[1]. These differences represent the continuation into later life of the well-documented social class differences in health status observed amongst the pre-retirement age groups.

There are significant methodological problems involved in quantifying the prevalence of dementia and other mental health problems in community samples. The varying methodologies and samples used often account for the varying prevalence rates produced by different studies. For both depression and anxiety there appears to be little significant increase with age. Depressive illness of clinical significance is observed in about 10% of those aged 65+, whilst the prevalence of anxiety is about 11% in those aged 65+[15]. For both conditions prevalence rates are higher in women than men. Dementia prevalence and incidence increase exponentially with age, regardless of the instrument used or sample studied[17]. A meta-analysis of 27 studies suggested that dementia prevalence increased from 1.4% at age 65–69 to 38.6% for those aged 90+[17]. However, even amongst the oldest age groups dementia is not universal.

For both chronic physical and mental impairment there are few data about how prevalence rates may be changing over time. Hence, in making comments about the health status of future cohorts of older people, we are extrapolating current prevalence rates. This may (or may not) be justifiable, as the health status of future cohorts of older people may be improved as a result of better living standards and access to medical care. There are two major stances concerning future patterns of mortality. Fries[19] argues that morbidity will be compressed into the last few years of life, whilst the competing argument suggests that future populations will show increased rates of disability as more and more "frail" people survive into advanced old age[20]. Whilst we cannot be certain if prevalence rates for chronic physical and mental health problems will change, and in what direction, in the

future, it is important to remember the limitations inherent in applying current health prevalence rates to succeeding generations.

POVERTY AND SOCIAL INEQUALITY

In contrast to the traditional views of later life as a time of poverty and deprivation[19], there has recently emerged the image of the "Well-Off Older Person (WOOPIE)". This image has portrayed older people as a newly affluent group who are benefiting at the expense of younger people. However, recent studies have illustrated that, for the majority of older people, poverty remains the norm, especially in advanced old age[19]. In Britain, one in three of those living in poverty are older people and rates of poverty increase with age, are higher amongst women than men and amongst those from the manual occupation groups[19]. The explanation of such high rates of poverty amongst older people is the low level of state pensions, the principal source of older people's income, and the lack of access by many older people to additional sources of income, such as occupational and private pensions[20–22].

PATTERNS OF FORMAL AND INFORMAL CARE

Older people are the main users of the formal health and social care services provided in Britain[9]. However, despite this the majority of older people do not regularly use formal care services. For example, 19% of those aged 65+ use hospital inpatient services annually, 6% are visited by a district nurse and 4% by a home help[9]. Even for the potentially most vulnerable (those aged 85+ living alone), the district nurse/health visitor is in contact with less than 15%[9]. For most daily tasks that older people (and indeed other age groups) need help with, the principal source of support comes from the informal sector, usually either a spouse or children[23]. Hence the family is, as it always has been, the major provider of care to the frail older person[23]. However, we still know little about the ties within families that promote the development of the caring relationship[24]. There is comprehensive research evidence which clearly shows that older people are themselves significant providers of care to each other[23] and younger age groups[23].

CONCLUSION

The research evidence now available illustrates that the common stereotypes of later life are both inaccurate and out of date. The majority of older people live in the community, in their own homes, and are integrated within a network of family and social relationships. The health status of older people is considerably better than the popular stereotypes, with chronic physical and mental impairment far from universal, even in the very oldest age groups.

Furthermore, although older people do use the health and social care services, the family remains their principal source of care. Indeed, older people are major contributors to the provision of care.

Moreover, within this less pessimistic review of later life, it is important not to treat older people as a single homogeneous social group. The experience of later life is greatly influenced by important dimensions of social stratification, such as gender, class and, increasingly in the future, ethnicity. It seems likely that such socially differentiating dimensions, especially ethnicity, will become increasingly important in determining the experience of future cohorts of older people.

Do Life Events Seem Less Stressful to the Old?

A. D. M. Davies

Department of Psychology, University of Liverpool, UK

INTRODUCTION

Problems in defining, measuring and interpreting the impact of a life event have been much discussed[1,2]. Where events occurring to older people are concerned, problems are compounded in that typically, mental health researchers assessing event severity are younger than the people assessed. A "social clock" view of development, however, assumes that the impact of an event depends on whether it is seen as normative or non-normative *for the stage of life*. The paradox is that older people are generally not the group that make the judgements of the severity of events occurring to older adults. A study was therefore carried out to see whether an elderly panel of raters accorded in judgement with a younger panel of four professional raters trained in the Bedford College LEDS scale, and whose ratings had been shown to be consistent and reliable[3].

METHODS

A group of 25 retired university and health service personnel was recruited to rate the severity of the events and difficulties that occurred to a sample of elderly rural people over a 12 month period. The present results refer to the ratings made by a randomly assigned subgroup of 10 (age range 65–82) who were thoroughly trained in the LEDS procedures. Their ratings were compared with those of a (non-elderly) psychologists' rating panel. After training, the panel met for six sessions over a 3 month period to rate 80 life events drawn from a pool of 289 events, which had occurred to an independent sample of 237 rural elderly people living in the community. The events were drawn in a counter-balanced way according to the consensus severity (threat) assigned to the professional panel (I = severely threatening, IV = little or no threat) within each of 20 blocks. Training for the older panel used definitions and guidelines from the Bedford College Manual, together with taped interviews, group discussion and rating practice with feedback about the professional panel's ratings. After all blocks had been rated, five blocks were re-rated to examine reliability (20 events). There was a minimum of 1 week and a maximum of 3 weeks between ratings. All but one participant showed significant agreement between the two ratings (as measured by Kendall's coefficient of concordance). The inconsistent participant's data were excluded from further analysis.

RESULTS

The distribution of severity ratings for the older trained panel over the four levels of event severity were as follows: I, 3; II, 27; III, 34; IV, 16. A one-way analysis of variance (ANOVA) comparing the mean ratings of the old trained panel with those of the professional panel showed that there were significant differences ($F = 5.6$, $P = 0.004$). *Post hoc* comparisons indicated that the old group rated events as less severe than the young group. Cross-tabulations showed that, although there was some agreement of the older and professional panels (weighted kappa = 0.31), the agreement with the professional panel was mainly about which events posed little threat. There was poor agreement for the crucial events of type I (severe threat). Of the 20 "severe threat" events presented, the distribution of ratings for the older panel were: I, 3; II, 6; III, 10; IV, 1. Most of these events concerned deaths of family members which, in general, the older panel (even though they had been trained in the LEDS procedures) did not see as particularly threatening.

CONCLUSION

The results provide support for the view that events such as deaths and severe illness events may be judged less threatening to older people, perhaps because they are seen as "on-time"[4]. Not all death events were rated equally, however. "Death of a spouse" and especially "death of a child" were regarded as more threatening than the death of a sibling or friend. However, in general the older panel rated stressful life events more conservatively.

ACKNOWLEDGEMENT

I would like to thank J. O. E. James and S. J. Wilkinson for their help in the collection of the data reported here.

Support Networks

G. Clare Wenger

Centre for Social Policy Research and Development, University of Wales, Bangor, UK

It is difficult to find any text in social gerontology which does not refer to social networks, care networks or support networks. In the 1980s, a shift in social gerontology research took place to focus on networks of support rather than whether or not elderly people have contact with each of a range of categories of relationship (spouse, daughter, brother, etc.)[1–6].

Support networks here are defined as those within the larger social network of the individual who regularly provide support in a range of contexts of day-to-day life, and include: members of the same household; relatives seen most frequently; confidant(s); and those people providing, or perceived by elderly respondents to be available to provide, emotional support, instrumental help, personal care or advice. Support networks may range in size from two to 22 but modally cluster around five to seven[4,7,8].

Women have been shown to have more expansive networks than men in a wide range of countries[9]. Research has shown that older people with strong social networks are happier and more likely to perceive themselves to be healthy[10]. Others have suggested that, for people with serious mental illness, social support promotes normality in life styles[11]. A review of the findings on social networks of older people[9] makes the following observations, which have significance for geriatric psychiatry. Dense networks (where a high proportion of members know one another) tend to provide better access to emotional support but may shield or prevent people from seeking professional advice. For example, Veiel[12] found that for some patients, psychological and emotional support in crises received from close relatives was associated with a subsequent increase in depressive symptoms. Loose-knit networks provide better access to resources, including professional care. Residential admissions are less common where there is a close supportive network but this can also be associated with the avoidance of needed professional interventions.

The radius of support networks tends to follow a bimodal distribution, with substantial numbers of older people having either all members within 5 miles or at least one member more than 25 miles away. Support networks typically have a core of family but also include friends, neighbours and home helps. Normative expectations of support for different relationships exist that are well defined but these are likely to be culturally specific. Such expectations are hierarchical. In the UK spouses top the hierarchy, followed by immediate family: daughters/sons and sisters/brothers. Following siblings come friends, and then neighbours. Extended family of grandchildren, nieces/nephews and cousins come below friends and neighbours[13,14]. Expectations are affected by the intervening variables of distance, gender and health. Long-term residents in a community tend to rely on local kin, while retirement migrants are unlikely to have kin nearby and have more diffuse networks[15,16].

The review of the literature referred to above suggests that older people may use different network members in different ways in emergency and non-emergency situations. There is evidence to show that vulnerable or stigmatized groups may be disadvantaged in network terms. Mentally ill people have smaller networks than others and the same is true for dementia sufferers. The more intimate (e.g. bodily care), personal (e.g. washing clothes) or private (e.g. financial concerns) the need of the elderly person (as defined by the culture), the more likely it is that this will be met by a family member. However, non-kin appear to be more important than family for morale, self-esteem and emotional support.[17,18]. A high proportion of members of the support networks of elderly people are themselves elderly and/or female. Those who are or have been married tend to concentrate most need for support on one member of their network (usually a spouse or adult child), while those who have not married tend to spread their needs throughout their networks, relying on a wide range of others for one or two types of support.

Based on longitudinal data from the UK[5], it has been shown that, contrary to expectations for largely elderly networks, the size of networks typically remains stable over time, suggesting some form of homeostasis. One exception to this is the support networks of married men, which tend to shrink with widowhood. The average change is equivalent to ± 1–2 over 4 years. However, with increasing physical or mental frailty, networks tend to shift to reflect more reliance on proximate kin, if available, or increasing use of formal services and/or growing social isolation[19].

Loss from networks is predominantly due to death or disability and gains come from the pre-existing social network, with members moving into the supportive core. Tensions in networks may arise from mismatch of expectations between the elderly person and the network member, i.e. where demands exceed normal expectations of the relationship or where different actors define the relationship differently. Mental illness, particularly the resultant cognitive dissonance experienced by network members, can result in network contraction as non-kin withdraw and kin tend to insulate the sufferer from non-kin contacts[19].

Several different typologies of the networks of older people have been developed in Australia[8], the USA[20], the UK[6] and Israel[21]. What is striking is the similarity between them. Each typology: (a) reflects a continuum from close-knit to loose-knit; (b) finds that density is related to the importance of kinship; (c) includes the identification of a household-focused adaptation, based on a privatized life style and a small network; (d) identifies an association with social class (middle-class networks are less dense); and (e) acknowledges the influence of neighbourhood type.

Support networks demonstrate a range of types, which vary in terms of: availability of local kin; levels of interaction with different categories of membership; and the degree of community involvement, as measured by voluntary association. This article focuses on the Wenger support network typology, developed in the UK and subsequently validated in other countries. The Wenger typology identifies five types of network[6], which have distinct parallels with the other network typologies. The five types of networks identified are summarized below. The first three types are based on the presence of local kin; the other two types reflect the absence of local kin:

1. *The local family-dependent support network* has a primary focus on close local family ties, with few peripheral friends and neighbours; it is often based on a shared household with, or close to, an adult child, usually a daughter. Community involvement is generally low. These networks tend to be small and the elderly people are more likely to be widowed, older or in less than good health.

2. *The locally integrated support network* includes close relationships with local family, friends and neighbours. Many friends are also neighbours. It is usually based on long-term residence and active community involvement in church and voluntary organizations in the present or recent past. Networks tend to be larger on average than others.
3. *The local self-contained support network* typically has arm's-length relationships or infrequent contact with at least one relative living in the same or adjacent community, usually a sibling, niece or nephew. Childlessness is common. Reliance is focused on neighbours but respondents with this type of network adopt a household-focused life style and community involvement, if any, tends to be low key. Networks tend to be smaller than average.
4. *The wider community-focused support network* is typified by active relationships with distant relatives, usually children, and high salience of friends and neighbours. The distinction between friends and neighbours is maintained. Respondents with this type of network are generally involved in community or voluntary organizations. This type of network is frequently associated with retirement migration and is commonly a middle-class or skilled working-class adaptation. Networks are larger than average. Absence of local kin is typical.
5. *The private restricted support network* is typically associated with absence of local kin, other than in some cases a spouse, although a high proportion are married. Contact with neighbours is minimal; there are few nearby friends and a low level of community contacts or involvements. The type subsumes two sub-types: independent married couples and dependent elderly persons who have withdrawn or become isolated from local involvement. Networks are smaller than average.

As a result of different network configurations and differing normative expectations for members, some networks are more robust in terms of the provision of the informal support they can provide. Different types of networks react in different ways to the common problems of old age[22,23]. Different network types have different strengths and weaknesses and nature of the risk is related to the type of network[24]. Network types have also been demonstrated to relate to levels of use of domiciliary services and to types of presenting problems[25,26]. Knowledge of network type can, therefore, be a useful tool in planning therapeutic interventions and a measurement instrument for use by practitioners has been developed[22,24]. This makes it possible to identify support network type on the basis of eight questions.

Recent research has paid increasing attention to the significance of network type for professional practice. It has been suggested that to achieve "real improvements in the quality of life", the relationship environment of people with severe, long-term mental health problems needs to be explicitly addressed by practitioners[27]. Other authors[28] make the same point in the context of bereavement. Network type has been shown to be strongly associated with depression but not anxiety[29].

High needs for intervention have been identified in the context of a firm diagnosis of dementia associated with networks that reflect low levels of social support[30]. Admission to long-term care of older people with dementia occurs sooner in all network types other than the family-dependent network. In network types without local kin, the network tends to become private, restricted in the face of dementia[31].

The distribution of network types has been shown to be related to neighbourhood or community. Typically, where population stability is high, those types of networks based on local kin and providing high levels of informal support are found. Where population movement is high, for example in areas where retirement migration is common, the proportion of more vulnerable network types is greater[13,15]. Because of the relationship with coping strategies, knowledge of the distribution of network types can be an important indicator for planning the mix of service provision, in the same way that the identification of the network of an individual can indicate the appropriate type of intervention and potential future outcomes.

World Statistical Trends and Prospects

George C. Myers

Center for Demographic Studies, Duke University, Durham, USA

The aging process relates to both individuals and the collective aggregates that they comprise, such as families and nations. The prolongation of human life has resulted in ever-increasing numbers of persons not only reaching the threshold ages defining old age, but living beyond. In most of the world's developed countries, at least four-fifths of the persons born today can expect to reach their 65th birthday and, of these survivors to old age, over 40% will reach 85. At the beginning of this century, only half as many (two-fifths) could expect to reach age 65, with only 14% of the survivors likely to live to age 85. The future will no doubt bring even further extension of life for greater numbers of individuals. A corollary of this development will be increases in the numbers of older persons in our populations, given the large size of future cohorts of persons reaching the older ages.

This remarkable achievement in extending life, largely a phenomenon of the twentieth century, has important consequences for the well-being of individuals and the societies in which they live. Most notably, we must be concerned with the implications of these trends on the life conditions of older persons and their impact on the social, economic, political and health institutions of societies. As many contributions to this volume emphasize, loss of intellectual functioning and the emergence of mental illness are not inevitable concomitants of aging. But the older population does have the highest frequency of cognitive impairments and disruptive behaviors of any age group and are least likely to be seen by mental health specialists[1]. Moreover, these conditions also command high levels of care and support from family and community networks. An increased awareness of the demographic context, both present and future, is necessary for furthering our understanding and treatment of these phenomena.

In this chapter, we provide a statistical treatment of the diverse dimensions of this aging process, particularly population aging, and how it is likely to evolve in the years ahead. Although population aging is truly a world-wide experience, for this volume we focus on conditions within the so-called more developed region (MDR), which include North America, Japan, Europe, Australia and New Zealand. It is in this more developed region that population aging has progressed the most in terms of the proportions of older persons in the population. Moreover, the countries in this region also have experienced major changes in the composition of the aged population itself. The data reported in this chapter are derived from the most recent population projections (medium variant series) of the United Nations, as assessed in 1998[2].

GROWTH OF THE OLDER POPULATION

The older population—persons 65 years and over—is estimated at 171 million for the more developed region in 2000. They represented 14.4% of the total population, about one in every seven persons. The number of older persons has increased by 45 million or 35% since 1980, compared with an increase of only 6% for the under-65 population. By the year 2050, the region's older population is projected to reach nearly 300 million, a numerical increase over the 50-year period of 128 million. As noted in Table 16.1 and Figure 16.1, the growth accelerates after the year 2010, as persons born in the post-World War II period reach the older ages, then subsides somewhat after 2040.

The growth rates for the older population over the total period greatly exceed those of the under-65 population of countries in the region. In fact, the younger population actually declines in number after the year 2010, as newly-aged cohorts advance into

Table 16.1 Population distribution by age group, more developed region, 1980–2050

	0–14	15–64	65–79	80+
1980	243	714	126	22
1990	236	768	144	31
2000	216	801	171	36
2010	196	820	192	50
2020	193	791	232	58
2030	187	749	274	72
2040	182	712	294	92
2050	177	679	299	102

the older population and are not fully compensated for by youths. Thus, the proportion of older persons in the total population is expected to steadily increase, reaching nearly 23% in 2030. This aggregate figure masks considerable variation among countries, with Japan (27.3%), and Italy (29.1%) expected to reveal the highest levels and Ireland (17.9%) and New Zealand (18.8%) at the lower end. Nonetheless, the proportion of older persons for all countries in the region is historically unprecedented. An added dimension of these changes in the age composition of the populations is the expectation that by 2015 the proportion of older persons will exceed the proportion of young persons aged 0–14 years, given realization of the assumptions regarding fertility introduced into the projections.

AGE AND SEX COMPOSITIONS OF THE AGED POPULATION

Not only has the region experienced overall population aging, but the older population has itself aged. The growth of the oldest old (persons aged 80 and over) has important implications in terms of the health status of this group of people and their need for health care and social supports. If the assumption is correct that the prevalence of mental health problems increases with age, then these trends toward aging of the older population take on added importance. Moreover, the incidence of the most severe mental disorders (e.g. senile dementia of the Alzheimer's type) is greatly manifested at advanced ages[3]. The percentage of oldest old in the total older population showed a marked rise in the 1980s, when it increased from 17% to 22%. It will steadily rise until the year 2010 (26%) and then will decline slightly to 24% in 2025. The decline reflects the large number of persons who will reach the older ages between 2010 and 2030. Nonetheless, the overall numbers of oldest old will nearly double to 72 million in the region over the 2000 figure.

A noteworthy feature of the older population in the region is the preponderance of women over men. In 2000, there were 153 older women for every 100 men and, among the oldest old, 226 women for every 100 men. These levels for both groups are likely to be somewhat attenuated in the future, as the aged population gains large new cohorts, but the imbalance will still remain.

COMPONENTS OF POPULATION AGING

While the overall age and sex structure of a population is affected by fertility, mortality and migration, the main factors producing changes in the older population result from the relative size of cohorts reaching the older ages and the survival of these older persons to further advanced ages. Although the major source of future growth results from the large baby boom birth cohorts that will enter the older population, as was noted previously, the improved chances of persons reaching old age and surviving to advanced ages have also been a potent force in producing the present and future growth[4].

The average life expectancy of a baby born between 1995 and 2000 and experiencing the age-specific mortality conditions of that period was 71.1 years for a boy and 78.7 for a girl[5]. To gain some perspective on these figures, the following levels were estimated for the period 1970–1975 and projected for future periods:

	Male	Female
1970–1975	67.6	74.7
2020–2025	75.5	81.8
2045–2050	78.2	84.2

There was an increase of 3.5 years for males and 4.0 for females in the 25-year period preceding 1995–2000 and gains of 4.4 and 3.1, respectively, projected for a similar time period to 2020–2025. The reversal in the projected survival by gender can be noted and this is carried over into the next period, when only minor life expectancy gains are forecasted. Aside from this questionable gender reversal, some also view the assumptions underlying the UN projections as rather conservative. In fact, a life expectancy at birth for females of over 84 years has already been attained in Japan and is likely to be exceeded in many other countries by the second decade of the twenty-first century.

The extension of life has meant that the remaining years of life after persons reach age 65 have increased markedly. For the USA, a surviving male could expect to live 15.7 years on average at age 65 in 1996 compared with 11.5 in 1900, a 36% increase[6]. The average female could expect to live an additional 19 years in 1996, a gain of 6.8 years or 55%. Moreover, 76% of men and 86% of women born in 1996 can expect to reach age 65, doubling the percentages in 1900.Thus, not only have more persons reached old age, but an increasing amount of one's life is being spent as an older person.

These improvements in survival have resulted from widespread reductions in communicable diseases and even declines in the lethal progressions of some of the predominant chronic, degenerative diseases. A noteworthy feature of overall mortality trends in the region has been the reductions in death rates at older ages. An emerging issue of considerable policy importance is the extent to which these improvements in longevity have been accompanied by increases in active life expectancy free of major chronic diseases, functional disabilities and institutionalization. While data are lacking to definitively establish past developments, there is evidence that active life expectancy has tended to increase, perhaps even keeping pace with improvements in overall life expectancy[7]. However, with increased population aging, the net result of these developments is the likelihood of increased numbers of persons at old ages with chronic co-morbidities and disabilities and, therefore, in need of long-term care and rehabilitative services.

SUPPORT STRUCTURES

The demographic parameters that relate most directly to these emerging issues concern the households and family conditions of older persons who are likely to need supportive assistance (care-receivers) and those who are potential care-providers. A number of complex demographic and social factors are involved in this matrix.

There has been a steady trend over time toward increased proportions of older persons being married and reduced proportions being single and widowed in the countries of this region[8]. Moreover, this development is true not only for the total aged population, but also for all age groups up to the most advanced. However, it should be noted that a much larger proportion of men than women are likely to be married, with the converse true of widowhood. These trends are a product of both the previous marital experience of persons in cohorts reaching the older ages and improvements in the joint survival of spouses. Nonetheless, there are strong signs that this pattern will change in the next century, as large cohorts of persons who are divorced or have never married enter into the older ages.

Another distinctive trend has been the increasing likelihood of older persons, both married couples and individuals, to live independently from other family members or non-relatives. This pattern of living arrangements reflects the smaller size of families resulting from prior declining fertility, as well as value preferences among older persons for independent living. However, these observations say little about the degree of contact among family

Table 16.2 Generational support ratios, more developed region, 1980–2050

	45–49/65–70	65–69/80 +
1980	0.62	2
1990	0.58	1.56
2000	0.64	1.41
2010	0.64	1.1
2020	0.48	1.23
2030	0.41	1.08
2040	0.37	0.8
2050	0.35	0.71

Source: United Nations, *World Population Prospects: The 1998 Revision*, Vol II.

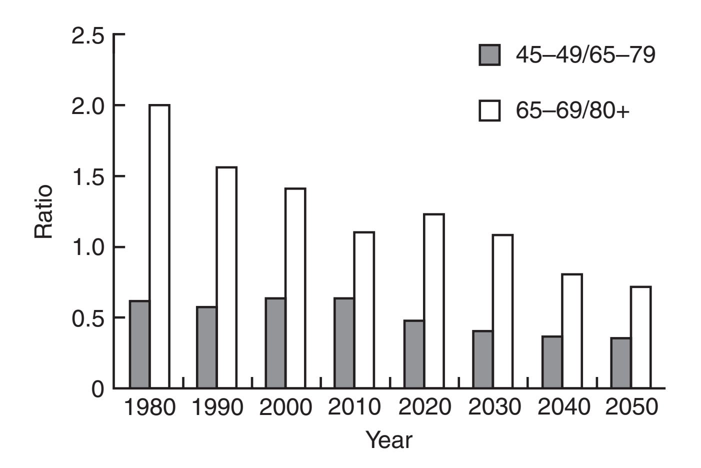

Figure 16.2 Generational support ratios, more developed region, 1980–2050. Source: United Nations, *World Population Prospects: The 1998 Revision*, Vol II

members or the strength of social networks, which appears to have remained strong.

Over the last few decades, increasing numbers of older persons have resided in institutions, although the proportions of such persons have not risen markedly in most developed countries[9]. While only 5–10% of older persons are in institutions at any given time, approximately 40% of persons will be institutionalized at some point in their lifetimes. Future prospects in light of the growing number of older persons living alone have given rise to considerable concern about the social, medical and economic issues of providing non-institutional vs. institutional care. Moreover, there is considerable policy debate over the optimal balance between family and state-provided care, whether in the home or in a more formal setting.

This brief review of trends suggests that there are major developments emerging from the growth of the older population and increased longevity that signal important changes in the potential care burden for vulnerable persons in the aged population. In turn, it raises questions about potential caregivers, most notably members of younger generations. A broad indication of the demographic indicators can be gained from examining ratios of the number of persons who are aged 45–49 to those aged 65–79. The former can be thought of as a group consisting of children of older persons. A second ratio relates two generations of older persons—those aged 65–69 to those aged 80 and over.

Table 16.2 and figure 16.2 show these two sets of ratios over the period 1980–2050. The importance of these ratios is not in their absolute levels, but in the relative levels over time. The younger generational ratios reveal little meaningful change up to year 2010, but thereafter decline steadily as the baby boom generation enters the older ages. The older generation ratios show more fluctuation. They have declined sharply from 1980 to the present and will continue downward to 2010. They show a rise in 2020, but then slowly decline to below parity through the projection period. In general, the shorter-term trends are somewhat reassuring in terms of the availability of potential caregivers but the longer-term trends reveal the increasing pressures on support systems. It should be noted, however, that such ratios do not inform us about the capacity of younger generations to provide assistance, which can be affected by kin relationships and involvement in employment that precludes extensive assistance.

SUMMARY

Population aging is a pervasive and seemingly irreversible process for countries in the world's more developed region. Not only will older persons increase dramatically in number and as a percentage of total populations, but dynamic forces will modify the socio-demographic and health status composition of aged populations as well. Like the Struldbrugs or Immortals of Swift's *Gulliver's Travels* the advantages of life prolongation have complex consequences, not only for the individuals involved but also for the societies in which they are found.

Demography of the Old: Implications of Recent Trends

Emily Grundy
London School of Hygiene and Tropical Medicine, London, UK

In most developed countries, at least 10% and in some cases more than 15% of the total population is aged 65 and over[1]. Recent projections suggest that by 2025 the proportion aged 75 and over will lie in this range; by then people aged 65 and over will contribute a quarter of the total in a number of countries including Japan, Italy and Greece, and over one-fifth in most of the rest of Europe. The proportion of "oldest old"—those aged 85 years or more—is increasing particularly rapidly[2]. As the risk of dementia is so strongly age-related, these changes will mean a large increase in the numbers affected unless strategies for prevention and postponement can be identified and implemented. However, there are also other implications of current demographic trends. Here I focus on changes in mortality and survivorship and also consider briefly changes in marriage.

The initial impetus for this ageing of the human world came from the transition to lower fertility that was set in motion in many Western populations in the last quarter of the nineteenth century and is now close to being a global phenomenon. More recently, the pace of population ageing, and the ageing of elderly populations, has been accelerated by marked declines in late age mortality; these are now the predominant motor driving the further ageing of populations with already old age structures[3].

The extent of this change is illustrated for five developed countries in Table 1. In England and Wales, France and the USA, male expectation of life at age 65 increased as much or more between 1970 and 1995 than in the preceding 70 years (or indeed, in the case of England and Wales, in the preceding century[4]). Among women too, the extent of improvement since 1970 is notable. Viewed from a cohort perspective, increases in longevity appear even more remarkable. Table 2 shows the proportion of each birth cohort surviving to the age of 80. Survival to later older age has increased dramatically reflecting not only large improvements in infant and child mortality (still very high in the nineteenth century) but also the more recent improvements in late adult death rates. Today, women of 80 represent not a select group of elite survivors, but *half* their original birth cohort. These improvements are not confined to the "young" elderly; death rates among the oldest old, including centenarians, have also dropped substantially[5,6].

Table 1 Further expectation of life at age 65, 1900–1995

These changes have sparked fierce debate about possible changes in the relationship between mortality and morbidity, the plasticity of the ageing process, possible limits to longevity and, of course, implications for health services. Less frequently considered are the implications for the family and support networks of older people and how these may interact with other changes in, for example, marriage and partnership.

The gender differences in mortality apparent in the tables underlie one of the most notable features of the older population, the preponderance of women. In the UK in 1998 the ratio of women to men at age 60–64 was close to parity (1.04) but rose to 1.85 at age 80–84 and 3.5 in the 90–94 year-old group. One consequence of this gender imbalance, compounded by the common pattern of women marrying men older than themselves, is that 65% of women aged 75 and over are widows, while 62% of men of this age are still married. If the narrowing of sex differentials in mortality continues, as is projected, the proportion of widows in this group will fall to 52% by 2021; however, by then 10% will be divorced (compared with 3% now) and a much larger proportion will have experienced divorce at some point in their lives (21% of those born in 1950 had already experienced divorce by the age of 40[7]). Those who have experienced marital disruption have poorer health in early old age[8], although this may be because of factors associated with both risk of divorce and poor health.

Changes in the age structure of populations also mean change in the age structure of families. Lower mortality increases the availability and duration of "vertical" kin networks. A recent (1999) national survey showed that 74% of people aged 80 and over in Britain were members of three-generation families and over one-third had living children, grandchildren and great-grandchildren[9]. Contacts between older people and their children and grandchildren are frequent; however, there have been very large decreases in the extent of intergenerational co-residence. In 1991 21% of women aged 85 and over lived in two- or three-generational households, compared with 42% 20 years earlier[10]. During the same period (1971–1991) the proportion of older people moving to institutions increased, while the proportion moving to live with relatives fell, suggesting some substitution of the former for family care[11].

Demographic changes of the type and magnitude, which here I have had space to allude to only briefly, require some thinking about roles, relationships and activities throughout the life course.

Most people now spend much longer as the parent of an adult child than they do raising minor children; increasing proportions will have step- and half-kin of various kinds and will live to know their great-grandchildren. However, expectations about these types of relationships may be confused. The increasing diversity of partnering and parenting patterns may also have implications both for mental health in later life and the support of those with mental health problems.

The Influence of Social Factors on Mental Health

David Mechanic* **and Donna D. McAlpine**

Institute for Health, Health Care Policy and Aging Research, Rutgers University, New Brunswick, NJ, USA

Social factors have an enormous influence on the life course, affecting development and socialization, the relative influence of families and peer groups, opportunities for work, recreation and social participation, and patterns of social integration and independence as one reaches the later years. With the rapidity of social change, persons living a normal lifespan are required to modify their expectations and behavior on many occasions if they are to adapt successfully to shifting social conditions. Transformations in technology, sexuality, fertility, family and work life, household structure and many other facets of life, also make it inevitable that different age cohorts will have diverse life experiences.

Almost every aspect of mental health and well-being are influenced by social factors and social institutions[1]. The effectiveness of social institutions, and the extent to which they build supportive relationships, coping capacities and personal commitment, contribute importantly to mental health outcomes. The dynamics of populations, and the distribution of persons at varying ages, also affect the productive capacities of nations, the prevalence of disability and dependence, and the capacity of a society to protect its citizens against the risks of disadvantage. Social attitudes and patterns of community organization can either encourage or inhibit full participation and meaningful roles for children, the elderly, the disabled or other groups, affecting functioning, quality of life and psychological well-being.

The discussion that follows focuses more on severe mental illness than on levels of psychological distress or emotional well-being. The distinction is not clear-cut because even depressive symptoms short of a clinically diagnosable disorder can have devastating effects on functioning and quality of life and are a major source of disability, surpassing in impact many serious chronic diseases[2].

Severe mental disorder, such as depression, bipolar conditions, and schizophrenia results from complex, but poorly understood, interactions between biological vulnerabilities and psychological and social influences. Adverse social and developmental factors may increase susceptibility to serious mental illness, or may contribute to triggering illness among vulnerable persons. Among persons with mental illness, social factors may significantly ameliorate symptoms, influence treatment patterns and enhance or impair quality of life. Most of the major social factors—age, gender, social class, race and ethnicity, familial arrangements and the like—are associated with mental illness, either by contributing to its onset or course or because of social selection factors. Moreover, there are complex interactions among social factors such that, for example, the impact of socioeconomic status or gender on mental health outcomes may vary by age or by birth cohort.

The epidemiology of illnesses that first occur later in life may be quite different from chronic conditions that persist through much of the life course. Understanding the occurrence of mental illness later in life, however, is complicated by the relationships between physical illness, drug use (commonly prescription drugs) and the occurrence of symptoms consistent with mental illness. Prescription and non-prescription drug use is high in elderly populations because of the prevalence of illness. The inappropriate use of pharmaceuticals among elderly persons is also common and includes physicians over-prescribing to older patients, self-medication and drug interactions[3]. Moreover, drug sensitivity changes with age-related changes in individuals' capacity to absorb and metabolize drugs; therefore, dosages effective in younger patients may be ineffective or excessively high for older patients. There continues to be considerable concern that institutional settings over-use medication in order to sedate and control patients. Drug reactions, including confusion, hallucinations, paranoia and mania, are common and may be inappropriately diagnosed as mental illness.

Schizophrenia typically first occurs in late adolescence or in early adulthood and may have a complex and fluctuating course. Follow-up studies of early-onset schizophrenia indicate that, with aging, the positive symptoms of schizophrenia abate or remain in remission for longer periods of time, and that for a significant minority of persons complete remission is possible, although the processes that lead to such outcomes are not well understood[4]. Selective mortality or the natural course of the disorder may be responsible for the relatively positive outcomes observed among older persons with schizophrenia. It is also possible that lowered personal expectations, the development of coping strategies, improved adaptation and learning how to avoid upsetting stresses also contribute to positive outcomes for persons with schizophrenia. On the one hand, persons with chronic schizophrenia bring into their later years life histories that are likely to be characterized by significant periods of disorder and disruption. On the other hand, they bring an array of skills and coping strategies, developed through dealing with illness over many years, and these may mitigate the potentially negative impact of the illness during later life.

Late-onset schizophrenia is relatively rare and little is known about its course[5,6]. The lack of evidence of late onset of schizophrenia and other psychoses among the elderly may in part result from diagnostic practices that give priority to co-occurring dementia and confusion that are highly prevalent in

*To whom correspondence should be addressed

later years. It has only recently been recognized in the USA, and there have been very few community-based studies examining outcomes. There is some suggestion, however, that those persons with onset later in life are able to function better in the community because occupational and social roles have not been interrupted by the disorder earlier in life[5].

There has been more research attention focused on depression during later life and although there have been widespread reports of a high prevalence among this population, epidemiological studies have not confirmed this impression[7]. But it is unclear whether the relatively low rates of depression at older ages are artifacts of epidemiological definitions and methods. Subthreshold negative affect appears very high in this population, leading many internists and geriatricians who care for the elderly population to believe that epidemiological estimates are biased and do not reflect the real situation. Depression is clearly different in elderly persons than in early and middle adulthood because of complex physical co-morbidities, decrements in function and relationship losses that occur in later life. Older persons are also less likely to acknowledge psychological manifestations of depression, see mental health treatment as more stigmatizing and resist referral to mental health specialists. Assessing depression within the constellation of physical concomitants that might be attributed to a variety of other conditions poses diagnostic challenges for the general physician. There are presently a number of ongoing experimental efforts to improve the recognition and treatment of depression among the elderly in primary care[8].

Most studies examining depression among elderly persons have not dated the onset of the disorder. There is some suggestion, however, that biological or genetic vulnerability may play a lesser role in the etiology of first onset of major depression or bipolar disorders late in life than earlier[9,10]. Late-onset depression and bipolar disorder appear to be triggered more commonly by medical and neurological co-morbidities, while onset earlier in adulthood is more strongly correlated with the occurrence of environmental stressors[10]. Much remains to be learned about the etiology of late-onset disorders but the role of social factors will vary with age.

Recent research reports a gender difference in late-onset schizophrenia, with older women having greater risk[5], although the reason for this difference remains unclear. There is also a gender difference in depression but, unlike schizophrenia, it develops in early adolescence and persists across the life course. The relationship is a complex one and is a matter of continuing controversy. Since abuse of alcohol and drugs and violence are more common among men, and depressed affect more common among women, some explain the two-fold prevalence difference in terms of varying gender-related reaction patterns[11]. Others have argued that the higher rates of reported and diagnosed depressive illness in women result from a greater prevalence of more common and less serious symptoms of depression reported by women, such as sadness and crying, and their greater willingness to report affective symptoms[12]. The issues remain unresolved, with different views depending in part on varying conceptions of the nature of depressive disorders.

Whatever the eventual resolution of these issues, the data do suggest that women in later life are at greater risk for symptoms of schizophrenia and depression than are their male counterparts. At the same time, older women are more likely than older men to be without a partner and they also experience greater economic disadvantage, both of which may exacerbate the negative consequences of mental disorder.

There is a long-established relationship between socioeconomic status and severe mental illness and decades of debate about the relative influence of causative vs. selection factors for explaining the higher prevalence of schizophrenia among those of lower socioeconomic status[13,14]. The weight of the evidence supports the view that the impairment associated with schizophrenia prevents upward mobility comparable to one's age cohort and loss of social position because of difficulties completing one's education and maintaining employment.

Early onset of major depression or bipolar disorder may also impair upward mobility, but socioeconomic status also appears to affect the onset of major depression. A variety of studies suggest that the etiological significance of socioeconomic status in depression relates to the prevalence of major life stresses and persistent difficulties and the lower availability of coping resources and social supports[15].

Disadvantages associated with socioeconomic status put persons with mental illness at risk for a number of negative outcomes that are not directly associated with the illness. Inadequate housing or homelessness remain significant problems for persons with mental illnesses and compromise efforts to provide meaningful services, yet we know very little about these issues in older populations[16]. Economic disadvantage is also a substantial barrier to access to health services and prescription medications in countries without universal health coverage[17]. These problems may be accentuated in later life for those with limited resources.

Socioeconomic status also helps to explain differences in mental health outcomes for different race and ethnic groups in the USA. While there do not appear to be major race/ethnic differences in the prevalence of severe mental illnesses independent of socioeconomic status, these factors significantly influence the course of illness. In the USA, rates of services utilization are lower for Mexican Americans, Asian Americans, and African Americans than Whites, when need for services is taken into account[18]. Economic barriers to access to health services contribute to this gap between need and service utilization among certain race and ethnic groups. Cultural differences in attitudes toward mental health services, perceived stigma and discrimination may also play a role[19].

The importance of family for the onset and course of mental illness has been commonly examined. The onset of severe mental disorder early in life increases the likelihood of remaining unmarried, especially for men, and increases the risk of divorce and separation among those who do marry[20]. Thus, many persons with severe mental illness will enter their later years without the benefits of a partner to provide emotional and instrumental support.

Styles of interaction within the family are also important. Most of the research has been focused on schizophrenia and suggests that a highly involved critical orientation to the patient contributes to relapse[21]. Instruction of families based on these principles has been found to be useful in some controlled trials, and offers a conceptual basis for psychoeducational approaches[21,22].

Increasing research in mental health focuses on stress and the coping process and the role of social support in either buffering the effects of stress or independently contributing to emotional well-being. While such factors as stressful events, coping resources, intimate and instrumental relations and self-efficacy have all been found to be associated with variations in psychological distress, their significance for major mental illness is less clear. Moreover, the role of these factors is condition-specific. In schizophrenia, stress acts as a trigger, affecting the occurrence and timing of episodes[23]. In affective disorder, in contrast, stressful events and meanings assigned to these events appear to play a more causative role in conjunction with other factors[12]. There is recent evidence that childhood adversity, such as separation from parents or sexual and physical abuse, may trigger onset of depressive disorders well into adulthood[24].

While, in general, it is believed that social support is important, the forms of social support useful to varying kinds of patients at

different stages of their conditions remain unclear[25]. There is much research suggesting especially that intrusive forms of social interaction involving criticism may be detrimental to schizophrenic patients, and the relative protectiveness of intimacy, friendship and instrumental assistance in depression remain unclear. Social support remains a vague concept, having varying operational definitions. Contrasting views of social support explain some of the conflicting research results.

There is increasing research attention being given to the role of religion and religious participation in health outcomes for the elderly and a variety of studies suggest that different aspects of religious involvement play an important role[26]. The pathways through which such effects are manifested remain unclear, although there is increasing suggestion that the social supports and instrumental assistance that might result from religious involvement contribute to better health. Research in this area confronts difficult selection biases, in that persons in better health may be more able and inclined toward religious participation and that persons drawn to varying religious practices may be different in their personalities, attitudes and behaviors than those with lesser or no participation. Nevertheless, the research in this area is gaining rigor and is suggestive of potential pathways.

The focus on coping skills as an important determinant of adaptation in more theoretically orientated studies has found expression in the development of psycho-educational programs to assist chronic mental patients in their rehabilitation. Although the research is modest, it supports the value of problem-orientated educational approaches that assist patients to manage everyday life situations better[27]. Psychosocial research on the importance of self-efficacy has been translated into programs to increase patient empowerment. It has been suggested that such empowerment is an important feature of the success of some commonly studied rehabilitation programs[28]. Increased empowerment may be an important factor, ameliorating the negative impact of highly regimented settings, such as nursing homes and other custodial institutions, but its therapeutic role in the normal range of life settings is yet to be established[29].

Social factors shape the processes through which individuals and families define illness, evaluate its meaning and significance and make decisions about needed care and appropriate practitioners. Epidemiological evidence shows that much serious mental illness is untreated, and those receiving treatment obtain services from a wide variety of practitioners. Processes of help-seeking are influenced by broad social beliefs about the nature of illness and what should be treated, characteristics of the individual and the social contexts in which mental illness occurs, and the organization of services and their physical, social and economic accessibility[1]. Members of varying age cohorts have been socialized differently in relation to the recognition of symptoms, appropriate sources of help and the social stigma of seeking care for particular types of problems. Selection from the community to varying types of service providers is a two-stage process, which depends on general factors affecting the inclination to seek assistance, and other factors more specific to the choice among alternative practitioners. A large proportion of all patients receiving care for a mental illness receive such care exclusively from general medical practitioners, and decisions affecting referral to the specialty mental health sector result not only from personal definitions and inclinations of patients and their families, but also from the organized pathways within a health care system, the ability of generalists to recognize mental illness in their patients and their attitudes to specialty mental health services. Patients with mental illness are referred more readily to specialized services when illness and illness behavior imply social risk and disruption[30]. Diagnosis, itself, is a poor predictor of the referral process.

Patterns of help seeking differ by age. The elderly are less likely to seek psychiatric care than younger adults, and probably are more reluctant to report affective symptoms to interviewers or physicians. In contrast, the elderly complain commonly in general medical settings of diffuse physical symptoms and vegetative symptoms characteristic of depression, and have relatively high rates of receiving prescribed psychoactive drugs. While somatization, as measured more formally, does not seem to vary by age, the elderly are more likely to present distress in a somatic idiom. Interpretation is complicated by the fact that the elderly have higher rates of ill-health and chronic disease than younger individuals, and it is difficult to sort out physical concomitants of chronic disease from somatization of psychosocial distress and depression. Psychoactive drug use also reflects physician behavior, which may be shaped by stereotypes of the elderly and other factors.

The social response to mental illness is influenced by such factors as general attitudes, values and ideologies, concepts of the nature of disorders and their causes, available treatment technologies, the structure of health and welfare services, and the system of social entitlements that a society makes available. The deinstitutionalization of the mentally ill has followed a different course in varying countries, but each of the above factors plays some role in every instance. In the USA, large-scale deinstitutionalization only became possible in the middle 1960s with the expansion of welfare programs that provided subsistence and payment for alternative residential care for mentally ill patients in the community. Some of the evident difficulties in community mental health services reflect cutbacks or fluctuations in welfare and housing entitlements[1].

The magnitude of serious mental illness depends on the distribution of the population, and the numbers of persons in age groups at risk for varying diseases and disabilities. The burden of mental illness depends not only on its magnitude but also on the types of social institutions and programs that help insulate patients, families and communities from its most disruptive stresses. The elderly population, and persons at very old ages, are growing in the USA and many Western countries. The dementias are increasingly important, and patients with such disabilities constitute a growing proportion of the severe mentally ill population. Depending on the constellation of institutional services and home-care programs, patients with dementia are treated in a variety of settings, some placing very large burdens on families and friends. The distribution of such burdens, and the definition of responsibilities, is a political process and a key social policy issue throughout the world.

For the last several decades, the nursing home has been the setting for care of persons who are greatly restricted in the activities of daily living, and a large proportion of persons in these settings have dementia and depression as a secondary condition[31]. Typically, admission to nursing homes occur when individuals are incapable of caring for themselves, when their physical and psychiatric problems create unmanageable burdens for their caretakers, or when community caretakers are no longer available. Admission is often triggered by such events as significant loss of function following trauma, such as hip fractures, confusion and wandering, and incontinence. Relatively few elderly with a primary diagnosis of mental illness, without dementia, are in nursing homes, although nursing home admission often exacerbates confusion, apathy and depression. Most elderly persons resist nursing home admission as long as they can, and increasingly alternative community settings and home-care services are provided to prevent or delay such admission[32].

Nursing homes, like the traditional long-term mental hospital, contribute to an institutional syndrome resulting from vulnerabilites of patients as they respond to decreased social participation, sensory deprivation, loss of efficacy and control over daily life decisions, institutional routinization and the like. There is persuasive evidence that efforts to keep patients involved

and participating in valued activities help maintain both mental and physical function. Many nursing homes fail to give these social aspects adequate attention, and patients spend much of their time in isolation and uninvolved. Nursing care may be the best treatment context for some patients who are seriously incapacitated and require a broad range of services difficult to provide in the home or in other community settings, but most impaired elderly benefit from settings that are more successful in sustaining independence and social engagement.

The capacity to cope effectively with mental illness depends on the organization of kinship groups and households, and the existing social institutions in a society. The growing prevalence of divorce, single-person households, small families, high female participation in the workforce, geographic mobility and other trends make it difficult to put increasing reliance on informal social networks for caretaking. Developing alternative structures that are financially viable and humane constitutes a growing challenge everywhere.

The Natural History of Psychiatric Disorders: Early-onset Disease in Late Life and Late-onset Illness

Judith Hays

Duke University Medical Center, Durham, NC, USA

Is psychiatric pathology fundamentally different depending on when in the life course it emerges? Is the heterogeneity that characterizes late life psychiatric disorders—their risk factors, presentation and course—partly resolved by distinguishing between ages of first onset? This chapter summarizes why studying the onset of psychiatric illness is so difficult and, in spite of that difficulty, what distinguishes the epidemiology of early-onset disease in late life from late-onset illness.

With respect to age of onset, the best-characterized DSM-IV disorder (and our primary focus in this chapter) is major depressive disorder (MDD). Some attention will also be directed to bipolar (BP) disorder and schizophrenia. Much less research has distinguished between early and late onset of dysthymia, "late paraphrenia", or delusional disorder; we touch only briefly on these subtypes. We do not discuss depressive and/or psychotic prodromes of dementia or psychiatric symptoms of other organic etiology, such as cancer or multiple sclerosis, with the exception of disorders related to cerebrovascular infarcts and depression secondary to cardiovascular disease.

Studies of the prevalence and correlates of early-onset vs. late-onset disorders are treacherous for methodological reasons that plague all psychiatric studies and all studies with retrospective designs: determining *who* has *what* disorder and *when* it was first detected. Sometimes there is no consensus on the criteria for a "case", because psychiatric disorders are based on clinical signs and symptoms and represent heterogeneous underlying pathophysiological and psychosocial causes. Subjects may be considered a case according to one set of criteria but not according to another. Elderly persons in particular report significant psychiatric symptoms without meeting diagnostic criteria. Not infrequently, emergent symptoms may alter a diagnosis of long standing. Thus, clinical populations, from which many study samples are drawn, may be non-representative of all affected elders, due to varying patterns of help-seeking, clinical referral and symptom trajectories. All elderly populations in communities and institutions, are subject to survival of the fittest, and early-onset subjects may be systematically absent due to death.

Determining the precise age of onset is also problematical. Recall of specific dates may be compromised by memory lapse or telescoping of events, cognitive impairment or a "reminder effect" associated with multiple episodes. Classification of early-onset vs. late-onset depends on the cut-point chosen, which is often unspecified in diagnostic schema; across various studies, cut-points have ranged between 20 and 60 years of age, although most use 45 or 50 years. For all of these reasons—diagnostic variability, selection bias, subject attrition and classification issues—estimates of the prevalence and risk of early-onset and late-onset disorders vary dramatically, as described below. Nevertheless, this chapter describes the state of agreement regarding differences in early and late affective and psychotic disorders.

AFFECTIVE DISORDERS

Major Depressive Disorder

The prevalence of affective disorders (MDD/BP) is lower among community-dwelling elders than among younger populations[1,2]. Prevalence estimates of late-life MDD from large studies (n51000) range between 1% (USA) to 3.7% (Finland), and prevalence of minor depression ranges from 8.3–23.2%[3–5]. In nursing homes, 5.9–16.5% of patients demonstrate clinically significant depression[6–7]. Among medical outpatients and inpatients, respectively, 5–7% and 10–20% may meet criteria for MDD[8–10]. Of affected elders in the community, van Ojen and colleagues[11] estimated that 70% may have had a first onset after the age of 65, i.e. late-onset depression (LOD) (Amsterdam, Holland). In the ECA (USA) study, the mean age of onset of MDD for subjects older than 65 years was 48.9 years, suggesting a large proportion of patients with late-onset[1].

The most provocative etiological findings regarding age of onset concern structural and functional brain abnormalities among LOD patients. Depressed elderly patients tend to have more abnormalities, particularly in the frontal regions, than do controls, although not universally[12–14]. LOD patients tend to present with more brain lesions than do patients with early onset of depression (EOD)[12], and subcortical and basal ganglia changes have been associated with greater severity in LOD[15]. These results from MRI studies are suggestive when paired with results showing increased vascular medical co-morbidity (e.g. hypertension, stroke and heart disease) among LOD patients[13,16]. Thus, risk of some subtypes of LOD may be attributable to vascular impairment and, by implication, preventable, using heart-healthy strategies such as diet, exercise and stress management. Where these results are heterogeneous, the inclusion or exclusion of subjects with cardiovascular histories may be a major factor[16,17].

At the other end of the modifiability spectrum, genotype may account for differences in the causal webs of EOD and LOD.

Krishnan and colleagues[18] found patients with the *ApoE3/4* allele to have later age of onset than those with *2/3* and *3/3*; conversely, Holmes *et al.*[19] showed that *ApoE2* protected against early onset, thus delaying the onset of depression into later life; other studies were inconclusive[20]. Although these findings conflict, the potential to locate common genetic risk factors for depression and dementia in late life continues to receive empirical attention. Pedigree studies have been much more univocal: elders with EOD consistently report more affected close relatives than do elders with LOD[16,21]. Some have suggested recently that age of onset may be a proxy for multiple risk factors, including structural brain changes, vascular medical co-morbidity, neuropsychological impairment, and family history of mood disorders[22].

Evidence of other non-medical risk factors for EOD and LOD is preliminary. Single studies show males and African-Americans at greater risk of LOD than females and Whites, respectively[23,24].

The clinical presentations of early-onset and late-onset disease among elderly patients are not strikingly different, with the possible exceptions of more apathy, anxiety, and psychotic features in LOD[21–25]. Most neurological tests also show no differences, with the possible exception of more impaired executive memory and visual naming ability in LOD[26,27].

On balance, prognosis may be slightly worse for EOD elders, although there are serious methodological difficulties with the evidence and significant heterogeneity of course in late life. Cole[28] summarized conflicting early findings of differential disease trajectories, and studies over the subsequent decade have continued to conflict, some showing EOD elders to have a more relapsing course, more frequent episodes and more treatment refractoriness, and others showing LOD elders to have less favorable treatment response, more cycling in and out of symptoms, and more psychiatric co-morbidity[29–31]. Still other studies demonstrate no difference. However, when treatment and outcome criteria have been standardized, neither LOD nor EOD elders appeared at increased advantage relative to absolute rates of 1 year outcomes (remission, relapse, recovery or recurrence), although weeks to remission were greater in one sample of LOD elders[22].

In a recent comprehensive review of the mortality of depression[32], only one of 57 studies compared mortality by age of onset. Rabins *et al.*[33] found no differences in mortality by age of onset in a small study. More recently, Philibert *et al.*[34] reported lower survival rates for subjects with LOD, especially women with onset later than their 6th decade.

Bipolar Disorder

Manic symptoms and bipolar disorder (BP) I and II are rarer in the population than depressive symptoms or MDD and are most rare late in the life course[35]. Fewer than 1% of US elders in the ECA study reported a 1 week period or more of elevated, expansive or irritable mood; lifetime prevalences of these disorders among persons 65 years and older were 0.1% for BPI and PBII in the same study[1]. Evidence from the UK suggests that the incidence of mania may be bimodal, with a detectable peak after 60 years[36,37]. Among elderly hospitalized psychiatric populations, 3.4–6.4% of all admissions and 12.5% of admissions for affective disorders present with mania; 12–16% of general hospital patients qualify for a bipolar diagnosis[35].

Historically, the two potential causes of mania were thought to be stressful life events and organic disease. Kraepelin[38] first noted the precipitating role of stressful life events in manic depression, and subsequent studies have implicated such events in the incidence of bipolar disease, particularly early-onset mania (EOM)[39]. Late-onset mania (LOM), on the other hand, has long been associated with both vascular and cerebral anomalies and their correlates, including obesity, head injury, EEG changes and dementia, with confirmatory evidence in more recent studies comparing older vs. younger bipolar patients[40] and LOM vs. EOM patients[39,41]. Yassa *et al.*[35] suggests that where significant life events distinguish LOM patients from aged controls, an organic substrate may have predisposed affected elders to a vulnerability to such events, and they then "react with a 'catastrophic' response (mania)" (p. 126).

A positive family history of bipolar illness has been more characteristically linked with EOM than with LOM patients[39,42–44]. However, methodological problems render this generalization suspect. Retrospective designs, low age-of-onset cut-off points and failure to distinguish between onset of depression vs. onset of mania are a few of the problems limiting the evidence[43]. Evidence of a gender differential in risk of early-onset or late-onset bipolar disorder has also been inconclusive[39]. Interracial comparisons of age of mania onset are not available.

Findings of differential clinical presentations of LOM and EOM in late life have not proved robust. The stereotype that LOM presented more often with "slow and fragmented flights of ideas, more rarely with elated affect, but more often with paranoid and aggressive features (p. 120)" was not confirmed in a summary of studies comparing the phenomenology of LOM and EOM in late life[35].

Prognostic differences by age of first onset of mania are difficult to substantiate[45–47]. In particular, differential survival may underlie the evidence of poor outcomes associated with LOM. To the degree that healthy social interactions are relevant to managing the course of bipolar disorder, recent preliminary findings are noteworthy: age of mania onset was higher among subjects with more positive assessments of social support and receipt of informal instrumental support[39,45].

PSYCHOTIC DISORDERS

Like affective disorders, late life psychoses (LLP) are heterogeneous, and the reach for consensus on diagnostic terminology has been torturous. In this summary we primarily discuss early-onset vs. late-onset schizophrenia (EOS/LOS), with brief mention of delusional disorder and entirely omitting discussion of alternative nomenclature (e.g. late paraphrenia) or subtypes less well characterized with respect to age of onset (e.g. schizo-affective and other psychotic disorders).

The lifetime history of schizophrenia is probably 41% in the elderly community population[48], with annual incidence of three new cases (and 45 relapses) per 100 000 elders[49]. Approximately 25% of elderly schizophrenics experienced a first episode after age 50[50]. Onset of delusional disorder, on the other hand, occurs later, with average onset in the 40s among men and the 60s among women[51]. Late-life incidence of delusional disorder is 15.6/100 000; prevalence in the elderly population is 0.04%[49].

Two powerful risk factors for LOS appear to be cerebral atrophy and brain injury, although a significant number of patients with late-onset LLP present with no apparent cerebral pathology[52,53]. Compared to affective disorders, there is less evidence that EOS and LOS elders present differently with respect to MRI findings[53] or cardiovascular medical co-morbidity. A positive family history of psychosis appears incrementally more likely among, respectively, non-psychotic elderly controls, elders with LOS, and elders with EOS[50]. Findings concerning ApoE differences in onset or phenotype are limited and inconclusive[54]. Female gender and sensory impairment may predispose to LLP[48,55].

There is considerable heterogeneity in the outcome of schizophrenic episodes. A significant number of schizophrenic patients improve and recover fully; others relapse intermittently; others remain chronically symptomatic[56,57]. Long-term studies include

mostly EOS patients, who make up the majority of geriatric schizophrenics. LOS, on the other hand, portends generally poor outcomes, although social adaptation may be better in this group, compared to EOS[50,58,59].

CONCLUSION

Overall, there is growing evidence that older patients with late-onset psychiatric disease are different from those who come to late life with a history of early-onset psychiatric illness. Their varying co-morbidity and symptom profiles suggest different (although potentially interacting) etiological factors, with genetic and/or social environmental factors predominating in early-onset disease and behavioral factors in later onset. More work is needed to describe any differential course, but social adaptation appears better for elders whose disease experience has been shorter.

Mortality and Mental Disorders

Michael E. Dewey
Trent Institute for Health Services Research, University Hospital, Nottingham, UK

INTRODUCTION

The topic of mortality and mental illness has a long history. Even if we discount the pioneering nineteenth century study of Farr[1] we can still go back as far as the study of Ødegård[2] among the contemporary studies. Both of these were, of course, patient-based and covered all ages.

Why should anyone want to study mortality and its relationship to psychiatric illness in later life? There are many questions we might want to ask:

- Are older people with psychiatric illnesses more likely to die than those without?
- Are older people with psychiatric illnesses more likely to die than younger sufferers after allowing for the general rise in the force of mortality with age?
- If they are more likely to die, in either case, why is this?
- Whether they are more likely to die or not, do they die from different causes?
- What theoretical issues does their risk of mortality raise?
- What implication for service provision does their risk of mortality, elevated or not, have?

There have been some attempts at studying these issues and a small number of relevant reviews. In this chapter there is no attempt to provide a bibliography of all the empirical studies. Instead a number of key references are chosen to illustrate themes.

DEATH CERTIFICATE STUDIES OF MORTALITY

A number of studies have used death certificate data to study mortality and the dementias. The primary goal of these studies has been to estimate prevalence without the expense of performing a community study. Only one study, that of Flaten[3] in Norway, gave estimates of prevalence close to those from community studies, and it has been generally accepted that such studies tell us about the death certification habits of doctors but rather little about the prevalence of dementias or the relationship between the dementias and mortality. There have been no such studies for illnesses other than the dementias.

PATIENT-BASED STUDIES

A full review of these was undertaken by van Dijk and colleagues[4] which should be referred to for details of this work. For reasons outlined in the next section, these studies will not be further discussed here.

COMMUNITY-BASED STUDIES

The primary source of information about the link between mortality and mental illness in this age group is the increasing number of community studies. Careful follow-up of well-defined series of carefully diagnosed cases has its place, but the selection that goes on between primary and secondary care gives rise to the risk that the information cannot be generalized. Since most cases of dementia and depression are managed in primary care, it is there that we must seek information on the mortality of cases of mental disorder. One of the most comprehensive reviews of the past few years was that of Schröppel[5]. She concluded that relatively little was known for either disorder.

The years since Schröppel's review have seen an explosion in studies relevant to dementia and depression. Two recent systematic overviews have synthesized those community mortality studies for dementia[6] and depression[7]. Disappointingly few of the primary studies provide effect sizes that can be combined, but there are enough to warrant the exercise for both disorders. For dementia, meta-analysis of six studies gave an odds ratio for mortality of 2.63 (95% confidence interval 2.17–3.21). There was weak evidence of a higher risk for vascular compared to Alzheimer's, for increasing risk with increasing severity of dementia, and for decreasing relative risk with age. There seemed no evidence of a sex difference. For depression, meta-analysis of 15 cohorts gave an odds ratio of 1.73 (95% confidence interval 1.53–1.95). There was weak evidence that men had a higher relative risk and that studies with longer follow-up have a lower risk.

There have been few studies of other diagnoses in older age, and there has been no systematic review of them. An account is given by Langley in her review[8].

CAUSE OF DEATH

Only one study[9] appears to have addressed the problem of the cause of death in community studies of dementia. Prior to this there had been a number of studies of patient cohorts. Although these doubtless have value, they do not help to solve the problem of the causes of differential mortality. For that we require a direct comparison between the proportion who die of cause X in the demented group with the proportion who die of cause X in the non-demented group. It seems so obvious that this is needed that it is surprising that only Jagger and her colleagues[9] have addressed the issue. They found that, relative to the general population, Alzheimer's disease sufferers had a lower risk due to age, for being manual social class, and for having a history of cancer, and a

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

higher risk for being male. This concords with the meta-analysis quoted above for age, but not for sex.

A detailed editorial[10] discusses issues in research into depression and mortality. In particular there is difficulty in separating association from causation.

METHODOLOGICAL ISSUES

A number of measurement issues have failed to receive appropriate attention. The studies of community samples use different methods of measuring differences in risk. Although for low risks the numerical difference between risk ratios and odds ratios is small, comparison would be simpler if studies reported in a common way.

Patient studies have not really addressed the issue of bias introduced by differential identification of the patient group and the controls. For instance, if date of diagnosis is used as the starting point for survival analysis, there will be a survivor bias and it will be difficult to identify controls in a similar way.

Studies comparing patient groups with the general population have also failed to account for the fact that demented people are part of the population, and if their death rate is very different from that of the population as a whole, and if they form a substantial part of the population, as they will beyond age 85, then the death rate quoted for the general population is an overestimate of that expected for non-demented people.

Few studies have put their results into any clear framework. For instance, the possibilities raised by epidemiologists[11] studying chronic physical illness, and implicit in the textbook relationship between prevalence, incidence and duration of illness, have hardly been explored[12].

DISCUSSION

Mortality has been one of the most studied endpoints in epidemiology, but the reader of the community studies will be struck by the fact that, for few of them, mortality was a primary end point. This has undoubtedly created the patchwork of methods of reporting which bedevils synthesis.

There has been a considerable literature relating mental disorders in younger adults to mortality[13], which has confirmed an increased risk for affective disorders (typical SMR 1.4) and schizophrenias (typical SMR 2.3). The studies quoted here suggest a similar, possibly slightly greater, risk for depression.

There is clearly an elevated risk for both dementia and depression, but there is little that can be confidently asserted beyond that. We do not know whether the risk is modified by other possible explanatory variables like age, sex, physical illness of functional status, neither do we know what causes of death account for the excess cases.

As yet, we do not know what would happen to mortality if we treated depression in older age more vigorously, or what would happen if universally effective treatments for dementia became available and we could treat people with dementia.

Long-term Outcome Studies of Psychiatric Disorders: Methodological Issues and Practical Approaches to Follow-up

Ann Stueve, John Toner and Anne V. Quismorio

Columbia University Stroud Center, New York, USA

What are the long-term outcomes of various types of psychiatric disorders? How do individuals, interacting with their environments, shape the course and consequences of mental illness? What environmental, personal and illness characteristics are associated with recovery and improvement? Are such characteristics disorder- or life stage-specific? A growing number of long-term follow-up studies have begun to address such questions. Their results both confirm and challenge accepted wisdom. Long-term outcomes of schizophrenia, for example, do seem to be worse on average than those of affective disorders[1]; at the same time, however, outcomes of schizophrenia are remarkably varied, undermining conceptions of its course as progressively deteriorating and chronic[2]. Substantive results from long-term follow-up studies are included in other chapters of this volume (*see* specific disorders). This chapter focuses instead on several basic methodological issues—case identification, co-morbidity, choice of comparison groups, sample representativeness and measurement issues—as they pertain to long-term follow-up studies (*see* refs[3–6] for elaboration). Our purpose is to alert readers to issues that potentially influence the interpretation and comparison of results. Issues associated with the statistical analysis of longitudinal data are beyond the scope of this chapter and are not included (*see* refs[6–8]).

There are two basic types of follow-up investigations: (a) prospective studies, in which the investigator defines a sample on the basis of current attributes (e.g. psychiatric or exposure status) and follows the sample forward in time; and (b) retrospective cohort designs, in which the researchers define the sample on the basis of some past characteristic (e.g. hospital admission during a specified time period, participation in an earlier study) and then reconstruct their subsequent life course up to some later point in time, using records, retrospective interviews, etc.[3] Retrospective cohort (or "catch up") designs require less time to complete than prospective studies covering a similar duration, but are more limited by the availability and quality of extant data and problems of recall. Both types of investigations have been used to elucidate the long-term course[9] and outcomes of psychiatric disorders[1]. The issues discussed below apply to varying degrees to both types of investigation.

CASE IDENTIFICATION

Case identification refers to the criteria and procedures used to determine what constitutes a case of the disorder under study and addresses the question, "long-term outcomes of what?"[10]. Without explicit specification of what constitutes a case, similarities and difference in observed outcomes across studies are difficult to interpret. For example, observed differences may reflect discrepancies in diagnostic practice; observed similarities may be illusory. Case identification is particularly problematic in long-term follow-up studies, where baseline data and diagnoses often predate the introduction of modern diagnostic systems and standardized assessment tools. One way in which investigators have dealt with this problem is to rescore baseline data (e.g. from hospital charts, case notes or interviews) using one or more current diagnostic systems (e.g DSM–III–R, ICD–10) and to select and compare cases based on these newer diagnoses[4]. This practice allows for comparison of outcomes using different nosologies and, insofar as criteria for inclusion and exclusion are reported, facilitates comparison of results across studies. Such benefits of rescoring, however, remain dependent on the quality and comparability of baseline data. Signs and symptoms that were never attended to or recorded obviously cannot be recovered, and their absence potentially introduces error into the rescoring process.

CO-MORBIDITY

A second issue concerns co-morbidity (i.e. the co-occurrence of two or more psychiatric disorders in an individual) and addresses the question, "to what extent are observed outcomes due to psychiatric conditions other than the one under study?"[5,22–25]. What appear to be differences in outcomes of schizophrenia, for example, may be due in part to differences in the prevalence and combination of secondary conditions. Here, too, the assessment of co-morbidity and its ramifications is particularly difficult in long-term follow-up studies, because outcomes may be influenced not only by secondary disorders recorded at baseline but also by the onset and recurrence of other disorders between baseline and follow-up. While some assessment tools [e.g. Schedule for Affective Disorders and Schizophrenia—Lifetime(SADS-L)] generate the data needed to make lifetime diagnoses, sample attrition and reliance on informants may impede reliable assessment of interim conditions for substantial numbers of subjects.

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

CHOICE OF COMPARISON GROUPS

The counterpart of case identification is the designation of comparison groups and addresses the question, "long-term outcomes of disorder X compared with what?" Comparison groups provide benchmarks for interpreting measures of outcome. What comparison groups are appropriate depends, of course, on the research question under investigation and includes, among others, samples of "normal" individuals, of individuals with other psychiatric or medical conditions, or population norms, if available. Comparisons may also be made on the basis of some risk factor (e.g. age of onset) or treatment of interest. What is important to remember when selecting comparison groups and interpreting results is that members of the case, or target, group may differ from those of the comparison group in ways other than the disorder or risk factor of interest, and these "other ways" may account for subsequent differences in outcome and course. Thus, it is important to assess whether comparison groups are comparable to case groups on extraneous dimensions that could influence outcomes.

SAMPLE REPRESENTATIVENESS AND ATTRITION

The representativeness of the sample at baseline and follow-up addresses the question, "to what extent and to whom are results generalizable?" Most current long-term follow-up studies are based on patient samples selected from hospitals, other treatment settings, clinician caseloads or case registries. Selection into treatment, however, is not a random process[11]. Treatment rates have been shown to vary by type of disorder[12], social and demographic characteristics of individuals[12,26], historical period[13], service delivery system and country. In addition, within a catchment area, patients are sorted and filtered into different types of treatment settings (e.g. public vs. private). Thus, the life trajectories of treated subjects may differ not only from those of untreated cases but also from those of patients treated in dissimilar settings.

More significant is the problem of sample attrition, whether due to death, inability to participate, refusal or failure to trace. This is because subjects lost to follow-up tend to differ in systematic ways from those who are located and interviewed[3,14]. Researchers often attempt to assess the type and degree of bias by comparing respondents and non-respondents on baseline characteristics; however, as Kelsey *et al.*[3] note, "the only way to ensure that bias stemming from loss to follow-up does not distort the study results is to minimize losses through intensive efforts to locate each cohort member" (p. 109). In addition, by reducing sample size, attrition reduces the statistical power of analyses to reliably detect outcome differences. With effort, several long-term follow-up studies have successfully minimized sample attrition[15]; the training and organizational strategies used have been summarized[15,16].

MEASUREMENT OF OUTCOMES

The measurement of outcomes is clearly central to long-term follow-up studies and raises the question, "on what dimensions and how should outcomes be assessed?" Many different measures of outcome have been used in follow-up studies, including measures of symptomatology, hospitalization, role functioning, impairment of social relationships and recovery[1,17,18]. Reliance on single global indices of recovery have proved largely unsatisfactory. Such indices are not only difficult to compare across studies but also imply an overly uniform picture of subjects' functioning. Subjects who fare poorly in one life domain (e.g. employment) often fare better in others (e.g. symptom profile)[18], and such discrepancies are masked by single global indicators of recovery. Even seemingly objective, domain-specific measures (e.g. unemployment or rehospitalization rates) can be difficult to compare across studies if they are influenced by setting specific economic conditions or social policies[4,19].

Sample attrition further complicates the measurement of outcomes. How should outcomes be assessed for subjects who are deceased or unlocated at follow-up? Investigators often rely on informants and/or records to provide information. However, in addition to raising ethical considerations, informants not only differ from subjects in their access to (and probably recall of) relevant information but also assess subjects' status from different perspectives. Records, too, may not contain the data of interest and, like informant reports, differ in perspective from subjects' self-reports[3,26]. In light of such considerations, it is important to follow the advice of Bromet *et al.*[4] and ". . . be cautious in comparing results across studies without carefully ascertaining both the definition of outcome and the criteria used in implementing that definition" (p. 154) (*see* refs[5,17] for elaboration).

MEASURES OF INTERVENING VARIABLES

The longer the time interval between baseline and follow-up, the more likely that intervening events and circumstances play a role in determining outcome status. Measurement of such events and circumstances addresses the question, "what are the interim processes and mechanisms that account for observed outcomes?" Here prospective designs have an advantage over retrospective cohort studies because measurement of potentially mediating and confounding variables can be explicitly built into both baseline and follow-up data collection, and time intervals between follow-ups can be chosen with intervening mechanisms in mind. Retrospective cohort designs are more dependent on the availability of records and/or the recollections of subjects and informants, which are vulnerable to recall and reporting biases[3,20,21,23]. Problems associated with reporting and recall are not avoided by prospective studies, however, especially when intervals between follow-ups are long.

PRACTICAL APPROACHES TO FOLLOW-UP

Smith and Watts[27] provide a thorough summary of methods for locating absent and deceased subjects. Their review of available procedures emphasizes the use of electronic databases as effective means for identifying the location and vital status of lost subjects. Various tools for locating participants lost to follow-up are currently available.

Sources for Locating Patients Assumed Alive

The US Postal Service is a convenient source of information when investigators are faced with outdated addresses. Upon request, an updated address can be obtained as long as the request is made within the year that the individual moved.

Incorrect telephone numbers can be updated by contacting the telephone operator for information on new telephone listings. Unlisted telephone numbers may be obtained, depending on the policy of the telephone company. White-page listings for the entire USA are available for purchase on compact disk (CD-ROM). Compact disks are updated yearly and are relatively affordable. Telephone numbers can also be updated by use of the

crisscross (or reverse) directory, which lists telephone numbers by address.

The Internet serves as an effective and cost efficient method of locating absent subjects. Various websites contain an extensive amount of information regarding residential listings. Internet sources differ by the type of information required to perform a search. When utilizing online databases, Smith and Watts[27] suggest that: "It is important that the investigator try each source before moving on to the next site. Failure to locate a number on one site does not mean that a search of another site will be fruitless" (p. 434). Some examples of current websites include:

www.infoseek.com
www.semaphorecorp.com
www.databaseamerica.com
www.four11.com
www.yahoo.com/reference/whitepages
www.angelfire.com
www.yahoo.com/search/people
www.switchboard.com
www.whowhere.com
www.lookupusa.com

The Department of Motor Vehicles can provide useful information on an individual, including one's address, date of birth and social security number, and can select physical characteristics; however, investigators must be cognizant of state-specific limitations and restrictions on public access to information. Similarly, voter registration files are restricted in certain states, yet careful review of files, when available, can produce useful information.

TRW, TRANSUNION and EQUIFAX, the nation's major credit bureaux, can provide vital information on patients, such as current and previous addresses, social security number, birth date, employer and spouse's name. Each of these credit-reporting services offers affordable products for assessing patient status. TRW offers TRW Social Search and TRW Address Update. Transunion offers TRACE, TRACE*plus*, ReTRACE and the ATLAS. Equifax offers DTEC and ID REPORT. Each product can successfully provide essential data but differs by the specific information generated and what is required for initiation of a search. Utilization of these credit bureaux is legal, offering comprehensive, affordable, time- and cost-efficient means for locating patients.

Information brokers may also be of use in attempting to locate missing subjects. Information brokers have access to varied sources of information, yet are typically costly options. As a result, it is recommended that researchers assess the necessity to locate their subjects prior to selecting such alternatives[27,29]. Similar sources of information may be available outside the USA.

Sources for Locating Patients Assumed Deceased

Various services are available for locating individuals who are believed to be dead. The National Death Index (NDI) identifies the states in which death occurred, the corresponding death certificate number and the date of death. The NDI file provides information for all 50 states, the District of Columbia, Puerto Rico and the Virgin Islands. The NDI database is updated annually and begins with deaths occurring in 1979.

NDI users can apply for NDI*plus*, an optional service that, in addition to the aforementioned information, provides details on the underlying and multiple causes of death for deceased patients. Procedures for requesting information through NDI vary by state. Prospective NDI and NDI*plus* users must submit an application form to the National Center for Health Statistics. Information regarding NDI and NDI*plus* can be obtained by contacting:

National Center for Health Statistics, Centers for Disease Control and Prevention, 6525 Belcrest Road, Room 820, Hyatsville, MD 20782-2003, USA.
Tel: (301) 436-8951, ext 109 or 101; fax: (301) 436-7066: e-mail: ROB3@CDC.GOV

The Equifax Nationwide Death Search provides information on deaths since 1955 from data compiled from the Social Security Administration. Search results will produce birthdate, date of death and state and zip code at death. Equifax is updated continuously and is therefore recommended for obtaining data regarding recent deaths. Furthermore, because records are available beginning in 1955, Equifax is potentially more useful for some retrospective cohort designs than the NDI[28].

Other sources for identifying deceased subjects include the Death Master File from the Social Security Index[27,29]. This information can be accessed at www.ancestry.com.

Contact information for additional services includes:

Social Security Administration's Death Master File, US Department of Commerce, Technology Administration, 5285 Port Royal Road, Springfield, VA 22161, USA.
Tel: (703) 487-4630

Equifax Credit Information Services, PO Box 105835, Atlanta, GA 30348-5835, USA.
Tel: (800) 944-6000

Trans Union Corporation, PO Box 8309 File 99506, Philadelphia, PA 19101-8309, USA.
Tel: (610) 690-3126

CONCLUSIONS

Long-term follow-up studies provide a useful vehicle for investigating stability and change in the course and consequences of psychiatric disorders; they raise a number of methodological and practical considerations as well. In this chapter we have tried to highlight basic methodological issues and practical approaches that bear on the interpretation and comparison of research findings and to reference practice approach and texts that address the issues in greater detail.

The Importance of Multidimensional Assessment in Clinical Practice

M. Robin Eastwood* and Abhilash Desai
*(*Formerly at) St Louis University Medical School, St Louis, MD, USA*

In many ways, geriatric psychiatry is a paradigm for contemporary medicine. A multidisciplinary team is required to address the complex range of assessment and treatment issues. After all, older people usually have more than one medical illness, are on several medications and may have considerable limitations (vision, hearing, mobility, cognition, finances).

According to Eastwood and Corbin[1], "the problems presented in the assessment and treatment of geriatric psychiatry patients may be best solved by a team composed of members with diverse professional training, meeting frequently to plan investigations, discuss findings and formulate coherent and comprehensive treatment plans. Such a group must function with little overlap of tasks and few interdisciplinary jealousies, be problem-orientated and exercise communication skills in order to be effective and efficient. Although the physician typically chairs team meetings and takes medical and legal responsibility, each member of the team must make a definite contribution, either in direct patient care, or with technical and back-up services", and "Whatever the level of sophistication, a geriatric psychiatry unit should be able to provide an holistic and eclectic approach to assessment of the patient".

For each patient there may be several assessments, each with a definite purpose. Pre-admission assessment in the home is valuable for evaluating functional level and the appropriate level of care. Admission assessment may be necessary to make a diagnosis and treatment plan. Follow-up assessment helps monitored treatment effects and overall outcome. The following health care professionals are required in the therapeutic team:

1. *Psychiatry*. Geriatric psychiatry is best practiced in a short-stay, 10–15 bed unit. Ideally, the unit should be free-standing for the elderly alone. Some would ague, because of the medical risks and need for specialist consultations, that the unit should be in the general hospital. The psychiatrist brings together the psychosocial and biological aspects of medicine and is preferably a geriatric psychiatrist. The amount of training received in a general psychiatry residency is inadequate to qualify as a geriatric psychiatrist. Conversely, a full fellowship is not necessary and a separate 6 month rotation is probably sufficient.
2. *Primary care physician*. It is useful to have a primary care physician on the team. This person can help identify medical problems, and suggest tests and medication to deal with these. They can help in the initial phases of assessment. The pace of research makes it difficult for a psychiatrist to keep up satisfactorily with new medications in other specialties and even for common illnesses like hypertension and diabetes.
3. *Consultation team*. It is useful for the geriatric psychiatry group to offer consultation services to other parts of the hospital. Looking for cases of delirium, dementia and depression to treat or to transfer to the geriatric psychiatry ward is a useful way of doing consultations and sharing good relations with other specialties.
4. *Nursing*. Optimally, the same nurse should be responsible for initial contact, inpatient care and follow-up. With this familiarity, the nurse can be responsive to presenting problems of safety and security, prostheses, fluctuations in daily activity, signs of therapeutic response and drug or other sensitivities.
5. *Social work*. The social worker can assess the strengths and weaknesses of the patient's current social network, and evaluate the potential for benefit from individual, family and group psychotherapy. The social worker should be able to provide individual support to the patient and family members.
6. *Occupational therapy*. The occupational therapist can evaluate the patient's response to social, physical and intellectual stimulation and self-care and instrumental activities of daily living. Occupational and leisure needs can be linked to community agencies upon discharge. This therapist should be able to help patients and their families with activities (music, storytelling, group activities, such as playing various games) that can be used to help cope with problem behaviors and emotional distress.
7. *Psychology*. The psychologist can critically determine global and specific intellectual deficits and help manage certain behaviors.
8. *Pharmacy*. The pharmacist is vital in monitoring drug levels, interactions and reactions in order to avoid the problem of delirium.

It is also advisable to have the consulting services of such specialties as internal medicine, cardiology, neurology, ophthalmology, otolaryngology, urology, physiotherapy and dietary science.

The team faces a variety of diagnostic syndromes. These include dementia, affective disorder, delusional disorder, neurosis and personality disorder, alcohol or drug abuse, and delirium. Each of these requires a standardized diagnostic, treatment and management protocol, all subject to measures of efficiency and efficacy.

Classification of Dementia and Other Organic Conditions in ICD-10

A. Jablensky and J. E. Cooper

Department of Psychiatry and Behavioural Science, University of Western Australia, Perth, Australia

The classification of mental disorders in the Tenth Revision of the International Classification of Diseases (ICD-10) is different from its predecessor, ICD-9, in several ways. In addition to a revised content that reflects the most important recent advances in research and clinical practice, it is presented in different versions for different types of professional users. The differences are, however, in degrees of detail and the versions are compatible with each other, since they are all derived from the same basic document (*Clinical Descriptions and Diagnostic Guidelines*, WHO, 1992)[1].

THE USES OF ICD-10

ICD-10 has necessarily retained its historical purpose of facilitating the recording of national and international statistics of morbidity and mortality, but now has the added values of also being designed as a uniquely international aide to clinical work, teaching and research. It achieves these objectives by means of an updated list of diagnostic rubrics, a set of glossary-type definitions of disorders and additional explicit diagnostic criteria. The latter have been developed in two versions: (a) clinical diagnostic guidelines for routine use, allowing sufficient flexibility and discretion in the application of "clinical judgement" in the hospital ward or the outpatient service; and (b) diagnostic criteria for research (ICD-10-DCR), providing stringent decision-making rules to increase the specificity of diagnostic classification and thus ensure a high level of sample homogeneity for the purposes of clinical, biological and other research[2].

As a result of a great deal of collaboration between the advisers to the World Health Organization and the several Task Forces that assembled DSM-IV on behalf of the American Psychiatric Association during the last few years of the preparation of both the classifications, there are very few important differences between them. Since the same body of internationally published research experience and literature was available to both sets of experts during the processes of development, those differences that remain are mainly differences of opinion rather than of fact. Some differences reflect the need for ICD-10 to accommodate a much broader base of international experience and opinions than a national classification. In the development of ICD-10, experts from many different cultures and languages were involved from the earliest stages.

As in ICD-9, Chapter V deals with "Mental and Behavioural Disorders" and is intended for the recording of the clinical syndromes as presented and experienced by the patient. If a specific underlying cause of the disorder is known (or highly probable), additional codes should also be used from other chapters of ICD-10, such as: Chapter I, Infectious and Parasitic Diseases; Chapter II, Neoplasms; or Chapter VI, Diseases of the Nervous System.

DEMENTIA IN ICD-10

In ICD-10, the dementias are embedded in the section on organic and symptomatic mental disorders (codes F00–F09), which contains the following major rubrics:

- Dementia in Alzheimer's disease.
- Vascular dementia.
- Dementia in diseases classified elsewhere.
- Unspecified dementia.
- Organic amnesic syndrome, other than induced by alcohol and drugs.
- Delirium, other than induced by alcohol and drugs.
- Other mental disorders due to brain damage and dysfunction and to physical disease.
- Personality and behavioural disorders due to brain disease, damage and dysfunction
- Unspecified organic or symptomatic mental disorder.

In contrast to ICD-9, the distinction between psychotic and non-psychotic illnesses is of no taxonomic consequence in ICD-10, where disorders of different psychopathological expression are grouped together on the basis of established or presumed common aetiology. In the particular instance of section F0, in which the dementing disorders are included, the underlying classificatory characteristic of "organic" is defined in the sense that "the syndrome so classified can be attributed to an independently diagnosable cerebral or systemic disease or disorder". The subsidiary term "symptomatic" is not used in the titles of individual disorders but it is included in the overall title of the block F00–F09. This is because it is widely used in many countries to indicate those organic mental disorders in which cerebral involvement is secondary to a systemic extra-cerebral disease or disorder. In other words, "symptomatic" in this context is a subdivision of the wider term "organic".

Another feature of ICD-10, as compared to earlier classifications, is the omission of any reference to age as a defining criterion of the disorders accompanied by a cognitive deficit. The terms "senile" and "presenile" are practically absent in the classification, and there is no provision for identifying any mental disorder as necessarily a result of ageing. The classification does, however,

allow the recording of an unusually early or late onset of the disorder. In other words, the mental disorders occurring in the elderly are no longer considered to belong in a separate category of morbidity. This is very much in line with research conducted in the past two decades, which has demonstrated that the relatively high prevalence of mental morbidity in the elderly in Western cultures is related to a wide range of psychosocial factors (e.g. social isolation, cultural uprooting and institutionalization), as well as to physical co-morbidity, but that the aging process itself does not produce nosologically specific forms of disorders.

If section F0 of ICD-10 is used as a diagnostic decision tree, there is a choice of five entry points at the level of clinical syndrome: (i) dementia; (ii) amnesic syndrome; (iii) delirium; (iv) organic quasi-functional disorder (affective, delusional, hallucinatory or other); and (v) personality or behavioural disorder. Once a disorder is identified at this general syndrome level, the next step is defined by the diagnostic guidelines, which lead into more specific diagnostic categories. The diagnostic decision rules for dementia illustrate the point.

The syndrome of dementia is defined in ICD-10 by "evidence of a decline in both memory and thinking, which is of a degree sufficient to impair functioning in daily living", in a setting of clear consciousness. For a confident diagnosis to be established, such disturbances should have been present for at least 6 months. Deterioration of emotional control, social behaviour and motivation represent significant additional features but the overriding criterion is the presence of memory, learning and reasoning decline. The ICD-10-DCR (research criteria) add anchor points for a grading of the deficits into mild, moderate and severe, separately for memory and intellectual capacity. The overall grading of the severity of dementia is made on the basis of the function which is more severely impaired.

Once the presence of the syndrome of dementia is established, the diagnostic process branches off into the different clinical varieties of dementia typical of Alzheimer's disease, vascular dementia and dementia in diseases classified elsewhere (including Pick's disease, Creutzfeldt–Jakob disease, Huntington's disease, Parkinson's disease, HIV disease and a range of systemic and infectious diseases, such as hepatolenticular degeneration, lupus erythematosus, trypanosomiasis and general paresis). Dementia in Alzheimer's disease is subdivided into Type 1 (onset after the age of 65) and Type 2 (onset before the age of 65). Although the ICD-10-DCR criteria emphasize the ultimate criterion of the neuropathological examination and the supporting role of brain imaging, they nevertheless allow for a confident clinical diagnosis to be made if clear evidence of a memory and intellectual performance deterioration has been present for 6 months or more. The ICD-10 criteria for vascular dementia are broader than the corresponding DSM-IV criteria: they include not only multi-infarct (predominantly cortical) vascular dementia but also the subcortical dementias (Binswanger's encephalopathy being an example), as well as the mixed cortical and subcortical forms.

As regards the diagnosis of delirium, ICD-10 has abandoned the distinction between acute and subacute deliria; the condition is defined as "a unitary syndrome of variable duration and degree of severity ranging from mild to very grave", with an upper limit of 6 months' duration and a subdivision into delirium superimposed on dementia and delirium not superimposed on dementia.

The rubric "other mental disorders due to brain damage and dysfunction and to physical disease" includes disorders with "functional" characteristics (e.g. hallucinosis, catatonia, schizophrenia-like disorder, and mood disorders) that arise in the context of demonstrable organic illness, such as cerebral disease, systemic disorders and brain dysfunction associated with toxic disorders (other than due to alcohol or drugs). An important, not yet fully validated, addition to this rubric is the "mild cognitive disorder" attributable to physical co-morbidity (including HIV disease), which is defined as transient but nevertheless involving memory and learning difficulties.

Finally, personality and behavioural disorders due to brain disease, damage and dysfunction include familiar conditions such as organic personality disorder (the frontal lobe syndrome, but also other lesions to circumscribed areas of the brain), postencephalitic syndrome, postconcussional syndrome and some new entities, e.g. right hemispheric organic affective disorder (altered ability to express and comprehend emotion without true depression).

In conclusion, two features of ICD-10 should be emphasized. First, as already noted, it does not identify the mental disorders in the elderly as a separate or special category of psychiatric morbidity. In addition to the F0 section listing the organic and symptomatic mental disorders, psychiatric disturbances arising in the elderly population can be classified, according to their presentation and course, in any of the other major sections of ICD-10 (except for F8 and F9, which deal with developmental disorders and behavioural and emotional disorders occurring in childhood and adolescence).

Second, although ICD-10 is not explicitly a multi-axial classification, there are two ways in which multi-axial coding can be achieved if required. The simplest way is to use extra codes from the other chapters of ICD-10 in addition to those in Chapter V; any physical disorders present can be recorded by codes from Chapters I–XIX, and codes from the final two chapters can be used to cover other noteworthy aspects of the clinical picture. These are: Chapter XX, External Causes of Morbidity and Mortality (the X and Y codes, covering drugs causing adverse effects in therapeutic use, and injuries and poisoning); and Chapter XXI, Factors Influencing Health Status and Contact with Health Services (the Z codes, which include a variety of social, family and life-style factors). Another and more comprehensive option is to use the special Multi-axial System now available, which was developed by means of an international collaborative study organized by WHO Geneva[3]. This provides three descriptive axes: Axis I, Clinical Diagnosis; Axis II, Disablements; and Axis III, Contextual Factors. These Axes are a convenient re-arrangement of the chapters of ICD-10 listed above, with the addition of a brief set of ratings covering physical disabilities.

PROSPECTS FOR THE FUTURE

It is likely to be many years before the next edition of the international classification is ready for use, but meanwhile there are plenty of issues worthy of debate. Whatever form the classification takes, it seems likely that the principle of recording the clinical picture by means of Chapter V and the underlying physical cause by means of other chapters will remain. Research is now providing many clues about the exact place and the histological nature of the lesions in the central nervous system that give rise to the clinical syndromes, but the clinical syndromes themselves will not change, and will always need to be recorded.

The new non-invasive techniques for brain imaging, such as MRI, SPECT and PET scans, are demonstrating a variety of structural abnormalities in the brains of some (but by no means all) patients with the familiar clinical syndromes that are also present in substantial proportions of normal subjects. These changes are "organic" in a general sense of being something physical, but not in the way the term is used in the ICD (that is, to indicate a concurrent and diagnosable physical disorder). It will probably soon be time to abandon "organic" as a term to be used in a classification, and to develop new terms and concepts that will make these more subtle differentiations clear.

It should be possible to omit the "nested" categories of organically caused syndromes of depression, anxiety and

schizophrenia in future versions of Chapter V. Their presence breaks the rule (otherwise followed) that a clinical syndrome should have only one place in the classification. They were included because of a clinical demand for the convenience of being able to specify both a syndrome and its cause by means of only one code. Their omission would cause no loss, while improving the properties of the ICD as a classification. Even desk-top recording systems now have large capacities and increasingly sophisticated software that make them capable of handling many entries for each clinical encounter or spell of patient care.

Psychiatric Diagnosis and Old Age: New Perspectives for "DSM-IV-TR" and Beyond

Eric D. Caine
University of Rochester Medical Center, Rochester, NY, USA

Aging and old age confront the psychiatric clinician and nosologist with special diagnostic problems. Our present syndromology has arisen largely from studying disorders of young and middle-aged adults. It is being challenged now by the general aging of the population in Western as well as many Eastern societies.

Aging reflects evolving biological, psychological, and social processes. Fundamental alterations of central nervous system functioning color the psychopathological and pathophysiological significance of specific symptoms, while the psychosocial meaning of discrete life events changes as one moves across the age spectrum. Old age brings an increase in confounding systemic medical conditions. Thus, we are confronted with an array of yet-to-be-answered questions. What is the relationship between the mentally disordered who have grown old, and the old who develop mental disorders? Does later age of onset connote a fundamentally different disease process, even when the presenting psychopathology is generally similar? How do we separate idiopathic (called "primary" in DSM-IV) psychiatric syndromes from psychopathological conditions caused by defined disease processes? What must the diagnostician and treating clinician do to distinguish those psychopathological symptoms that are amenable to treatment from confounding medical symptoms that reflect systemic illness?

The development of the fourth edition of the American Psychiatric Association's Diagnostic and Statistical Manual (DSM-IV) provided an opportunity to begin considering such issues more formally. These types of questions were almost neglected in previous editions of the DSM, in part due to a lack of meaningful research data, and no doubt reflecting a lack of interest among many American psychiatrists in treating geriatric patients. However, the past 15–20 years have seen a surge in interest in the USA in psychogeriatrics, as evidenced by enhanced clinical training and sharpened clinical identity. The development by the American Board of Psychiatry and Neurology of an "added qualification" in geriatric psychiatry during the past decade crystallized this recognition.

There were relatively few changes in DSM-III or DSM-III-R that pertained to elders. Dementia and delirium were defined more precisely. The term "involutional" was dropped from the classification, due to a paucity of data supporting the qualitative distinctness of involutional melancholia. A criterion had been added in DSM-III to establish a maximum age of onset for schizophrenia at 45 years, but this was deleted in DSM-III-R as more evidence was made available to American writers that schizophrenia-like disorders emerge among older patients and are not solely caused by primary cerebral diseases.

Literature reviews and discussions that were part of the preparation of DSM-IV revealed that there was a continuing lack of rigorous clinical descriptive research in many areas of geriatric psychiatry. There was a dearth of data regarding the natural history of both late-onset disorders and early-onset disorders that persist or recur throughout the life course into old age. It was also apparent that there were insufficient epidemiologic findings to fully define the prevalence or incidence of many later life disorders. In the USA, this may have reflected, in part, an overly rigorous application of DSM-III criteria during the epidemiological catchment area (ECA) studies. Although these were valuable for describing the psychopathology of some elderly patients, the stereotypic use of diagnostic descriptors developed for younger patients had the unintended effect of excluding possible subjects from each of the rubrics. This process was compounded further by employing lay interviewers asking highly structured questions. Many of the critiques regarding traditional approaches to cross-cultural psychiatry (e.g. the problem of "category fallacy"[1]) are equally germane to studies that utilize criteria developed for one age cohort when characterizing the psychopathology evidenced by another. As a result, many recommendations for DSM-IV regarding later life psychiatric disorders were qualitative or impressionistic, more useful for specifying directions for new research but insufficient for substantially revising many of the diagnoses to be included in that new edition.

DSM-IV AND BEYOND

The major innovation of DSM-III was the development of a multiaxial system that provided clinicians with a wider array of descriptive categories for more completely defining their patients' problems. However, there was little evidence in either DSM-III or DSM-III-R that indicated a thorough understanding of the complex multidimensional diagnostic problems posed by aging patients. In contrast, DSM-IV began the process of addressing this deficiency by including for many diagnoses a discussion labeled, "Specific Culture, Age, and Gender Features" or "Specific Age and Gender Features". This approach allows some limited consideration of aging-related issues, but again, the sparse commentary in many of these sections also underscores how little is known about many related questions.

The following discussion reviews each of the DSM-IV axes, considering aging-specific topics. They point to areas of controversy that will need further study before inclusion in a future DSM-V. As well, they will highlight planned alterations for the forthcoming text revision of DSM-IV (''DSM-IV-TR'') with regard to the diagnosis and classification of neurodegenerative processes, such as Alzheimer's disease.

Axis I

DSM-III and DSM-III-R continued the tradition of distinguishing between ''organic'' and ''functional'' disorders. This conceptual typology had posited a difficult-to-maintain dichotomy, one that was poorly justified in light of modern research[2]. As well, ''organic'' diagnoses too often had been applied without any clear rationale. Instead, DSM-IV emphasizes a conceptual move away from concerns about the presence of structural pathology, or its absence, to a consideration of etiologic link.

It is more meaningful, both clinically and heuristically, to label a disorder as ''primary'' (i.e. idiopathic) when its cause is unknown, rather than using a term such as ''functional'' that implies a specific type of physiological or psychological mechanism. ''Organic'' arose in the nineteenth century after the detection of organ (i.e. brain) pathology. Research findings of the past 30 years have clouded any hope of using such a criterion for separating alleged psychological from alleged biological disturbances. DSM-IV expects clinicians to clarify whether a disorder is primary (i.e. idiopathic) or ''secondary'' or ''symptomatic''. (The text itself avoids using the latter designations, given controversy in the USA regarding their exact definitions.) A lengthy description is provided in DSM-IV to help clinicians reason whether there is sufficient evidence to attribute the etiology of a psychiatric syndrome to a definable disease process. Thus, one might diagnose ''mood disorder due to Parkinson's disease'' or ''psychotic disorder due to Huntington's disease'' where there is a decision that the psychopathology is a direct reflection of the fundamental pathophysiological process that causes Parkinson's disease or Huntington's disease.

While DSM-IV includes a chapter describing symptomatic psychiatric conditions, they are distributed throughout the text, grouped with the primary psychiatric disorders with which they share phenomenological features, forcing clinicians to consider differential diagnostic questions directly. Although the impact of this change extends beyond older patients, it has frequent application to elders, given their heightened rates of general medical conditions. Whether geriatric psychiatrists and other clinicians have, in fact, undertaken a more rigorous approach to considering etiological relationships because of the changes in DSM-IV remains to be defined.

Cognitive Disorders

Delirium, dementia and amnestic disorders were clustered together in DSM-IV as ''cognitive disorders''. DSM-III-R developed, perhaps inadvertently, very restrictive criteria for delirium that excluded a variety of patients whose clinicians were certain about the diagnosis, but unable to use the diagnostic label. Beyond traditional definitions employing attentional dysfunction and fluctuating consciousness, DSM-III-R required the presence of ''disorganized thinking'', as evidenced by formal thought disturbance. However, mildly delirious patients may not have rambling, irrelevant or incoherent speech. DSM-IV returned to a broader view.

While the successive editions of the DSM have been the primary classification for American psychiatry, ICD-9-CM (*International Classification of Diseases, 9th edn, Clinical Modification*) has been adopted by international treaty as the medical diagnostic coding system used by the US Government for all data collection and reporting regarding morbidity and mortality. In order to receive reimbursement from Medicare, for example, every clinician must report diagnoses in terms of ICD-9-CM codes. These range from 00–0999, and are organized in sections based upon the type of disease process (e.g. infectious and parasitic diseases, 001–139; neoplasms, 140–239), anatomic location (e.g. diseases of the digestive system, 520–579; diseases of the nervous system and sense organs, 320–389) or functional area (e.g. mental disorders, 290–319).

The entire system of diagnostic coding now is being revamped during the development of ICD-10-CM. This is intended to deal with the problem of ''double coding'' (e.g. diagnosing meningitis as both an infection and a disease of the nervous system) and other shortcomings, most notably an insufficient number of potentially available codes for future classification needs. Beginning with the completion of ICD-10 by the World Health Organization during the early 1990s, the most important change has been the adoption of an alpha-numeric coding system, in which letters are used to indicate the section of the ICD classification from which the code is drawn. Thus, infectious disease codes start with the letter A, neoplasms start with the letter B, etc. Codes formerly contained in the Mental Disorders section (290–309) will start with the letter F, while codes formerly contained in the Diseases of the Nervous System (320–389) will be included under the letter G. The ''clinical modification'' of ICD-10 currently being developed by the US National Center for Health Statistics, using this alpha-numeric system, will be adopted officially within the next several years. The most significant change for geriatric psychiatry will be the provision in ICD-10-CM of only one code for Alzheimer's disease, G30, instead of the double coding that was part of DSM-IV and ICD-9-CM. Although sufficiently similar to ICD-10 to allow cross-national comparison of health data, ICD-10-CM will have several significant differences in terminology and level of specificity.

Subtypes of dementia of the Alzheimer type (DAT) and vascular dementia (i.e. with delirium, with depressed mood, and with delusions) were first introduced into the DSM-III at a time when these categories were referred to as ''primary degenerative dementia'' and ''multi-infarct dementia''. These subtypes were later carried forward into DSM-III-R and DSM-IV. The expressed rationale for adding these subtypes had been parsimony of diagnosis, based on the assumption that these three conditions were fundamental manifestations of dementia. It did not make sense to require a clinician to use an additional diagnosis to describe what were considered to be aspects of the primary clinical condition. But neither DSM-III nor DSM-III-R provided explicit instructions about when to use specific subtypes, and a number of questions arose regarding their use. For example, did ''with depressed mood'' include full-blown major depressive episodes occurring during the course of Alzheimer's disease, or just milder forms of depression? Should ''with delirium'' include all forms of superimposed delirium, or just delirium thought to be directly due to Alzheimer's disease or vascular pathology? How should one diagnose delirium secondary to suspected drug toxicity in a demented patient? What should be one's approach to describing other commonly encountered symptoms or signs, e.g. delusions, hallucinations, agitation, or anxiety? When delirium, delusions and depressed mood occur simultaneously, which diagnostic code does one choose?

DSM-IV continued to use this subtyping with three changes. A new subtype, ''with behavioral disturbances'', was added in order to allow the user to indicate ''clinically significant behavioral changes (e.g. wandering)'', although this was not codable in any numeric fashion. The ''with delusions'' subtype

required that the delusions be the "predominant feature". Lastly, DSM-IV clarified that depressive presentations meeting criteria for a major depressive episode should be included under the "with depressed mood" subtype, in addition to milder forms.

Even with these changes, the basic reasoning behind the DSM-III, DSM-III-R and DSM-IV subtypes was flawed. Beyond including only a small portion of the array of behavioral, psychological or emotional signs, symptoms or syndromes that can be caused by Alzheimer's disease, the structured hierarchy of the classification implied that these manifestations were a *secondary* or *subordinate feature* of the cognitive symptoms and signs of dementia. Ample data now demonstrate that, when present, they are most often manifestations of fundamental brain pathophysiology, as much as memory or other cognitive dysfunctions. In sum, for a classification that was intended to guide therapeutics as well as communicate information regarding signs, symptoms and prognosis, the system did not work.

A change in coding adopted by ICD-9-CM rendered these subtypes obsolete. In anticipation of planned changes for ICD-10-CM, the October 1997 ICD-9-CM coding recommendations indicated that the preferred diagnostic code for Dementia of the Alzheimer's Type should be 294.1 (for "Dementia in Diseases Classified Elsewhere") instead of 290.xx. Thus, the three subtypes that had been coded with a fifth digit could no longer be captured. These changes are being used to revise the approach in DSM-IV as well.

When a patient has emotional, mood or psychological symptoms or signs that are in need of therapeutic interventions arising from Alzheimer's disease, the clinician will be asked to code these conditions on Axis I as one of the "mental disorders due to a general medical condition". As with other etiologically- or pathologically-defined medical conditions, Alzheimer's disease will be recorded on Axis III. Like other secondary or symptomatic psychiatric conditions, these problems must substantially interfere with a patient's functional integrity to warrant a formal diagnosis.

Beyond dementia itself, the secondary conditions to be coded on Axis I (with an associated Axis III diagnosis of Alzheimer's disease) include psychotic disorder, mood disorder, anxiety disorder, personality change (types include labile, disinhibited, aggressive, apathetic, paranoid, other, combined, and unspecified) and sleep disorder. As there are no data indicating that AD *causes* delirium, despite the frequent occurrence of delirium among patients with dementia of the Alzheimer's type, the clinician will be pressed to define the specific etiology of the delirious condition when possible. Sexual disorders due to AD also should not be diagnosed, again reflecting an absence of clinical or research findings tying Alzheimer's disease to sexual dysfunction. Those patients who are uncontrolled in their sexual behaviors can be captured under the "with behavioral disturbance" subtype. Thus, for a man with AD having dementia and delusions associated with combative behavior, one would use the diagnoses 294.1 and 293.81, the latter for Psychotic Disorder due to Alzheimer's Disease, with Delusions. For a woman with delirium superimposed on DAT, the diagnosis will reflect the presumed etiology of the delirium (e.g. delirium due to anticholinergic use is diagnosed 292.81, Anticholinergic-induced Delirium).

Starting in October 2000, a new fifth digit will allow one to indicate whether the dementia is "with behavioral disturbances" (294.11) or "without behavioral disturbances" (294.10). The inclusion of a codable behavioral descriptor and the conventions regarding the diagnosis of DAT and other symptoms due to Alzheimer's disease will be included in DSM-IV-TR, with an anticipated publication in May 2000. (The DSM-IV text revision project is an empirically-based updating of the text only, without any changes being made to the criteria sets.)

The term "*behavioral and psychological symptoms of dementia*" (BPSD) has not been adopted during the DSM-IV revision process. There are two explanations. The first relates to the label itself. It implies that the signs and symptoms in question are a direct outgrowth of dementia, which is not a fundamental disease process but itself a secondary clinical syndrome, rather than suggesting that the behavioral and psychological symptoms are due to AD-caused brain degeneration. The second reservation reflects a concern that behavioral, psychological and emotional symptoms and signs are not a unitary phenomenon. It is most parsimonious at this time to use the extant, discretely defined "mental disorders due to . . ." and avoid creating yet another unitary diagnostic label that has no established reliability or validity[4].

A major topic for discussion during the development of DSM-IV was a recommendation that "age-associated memory impairment" (AAMI) be included as a diagnostic entity, in keeping with criteria proposed to standardize the definition of aging-associated changes in intellect[5]. Aging-related changes in intellectual ability are robust and demonstrable psychometrically when comparing healthy older subjects with younger control groups, encompass a variety of tasks beyond those related to memory, and are at times troubling for particular individuals. However, doubts were expressed regarding the use of a disease diagnosis for a normative phenomenon. There were no objectively defined standards for establishing a cut-off or threshold to separate it from the earliest manifestations of specific diseases (e.g. the early manifestations of Alzheimer's disease). Indeed, review of available data suggested that mild intellectual declines *relative to age-matched peers* often presaged the development of progressive disease. In contrast, there was clear evidence that AAMI was *not* associated with significant functional or social impairment. Ultimately it was concluded that there were insufficient data to establish a formal psychiatric diagnosis of AAMI[6]. DSM-IV finally included "age-related cognitive decline" as a Z code designation, one of those conditions "not attributable to mental disorders that are a focus of attention or treatment".

Other Axis I Issues

Other Axis I disorders provided focal points for heated debate, but concrete recommendations for classificatory changes were difficult to establish in the absence of well-developed research findings. The problem of mood disorders was illustrative. DSM-III-R criteria amply described many of the features of severe mood disorders seen in elderly patients coming to outpatient clinics or hospital inpatient services. However, they were far less satisfactory for describing the features of affectively impaired patients encountered in the offices of primary care physicians, evaluated in nursing home settings or ascertained through community surveys.

Many suffer "subsyndromal" presentations, either dysthymic states that generally conform phenomenologically to dysthymic disorder but are not sustained for the requisite 2 years, or manifestations that include mood, ideational or somatic features of an affective disorder but without the array of symptoms needed to qualify for a strictly defined diagnosis. A diagnostic system that excludes the majority of potential patients fails to fully serve its descriptive function[7]. But suggestions for change remain incomplete and are not yet supported by a sufficiently large body of careful clinical research. (So-called "minor depression" was added for research purposes to the Appendix of DSM-IV, but it remains uncertain how to apply this construct to the conditions encountered among elders.)

The deletion from DSM-III-R of age 45 years as a cut-off for the onset of schizophrenia removed a major impediment for

diagnosing elderly psychotic disorders. However, many clinicians have found unreliable the attempt to distinguish between schizophrenia and delusional (paranoid) disorder, based upon the presence of "bizarre delusions". There is no standard by which one can decide when a delusion becomes "bizarre". Other grounds for distinguishing delusional disorder from schizophrenia are now being considered. Additionally, current criteria for schizophrenia require a significant functional decline during the course of the disturbance, but investigators have noted that many patients with late-onset psychosis maintain stability in their personal and social functioning.

It is rare to encounter elderly patients with pure generalized anxiety disorders. Mixed anxiety–depression is common, but it does not fit easily among mood disorders or among anxiety disorders. Although some continue to advocate consideration of a label such as "mixed dysphoric state", there has been no consensus. Growth in the use of serotonin reuptake inhibitors, and compounds such as extended release venlafaxine, has dampened the debate in practical terms, but their apparent effectiveness for mixed anxiety–depressive states sheds little light that clarifies the nosological confusion.

Regarding obsessive–compulsive disorder, post-traumatic stress disorder and phobias, there are few data available about their occurrence among elders to make any salient recommendations regarding diagnostic classification or modification based on aging-related changes in prevalence, presentation, course, co-morbidity or treatment responsiveness. In a similar vein, there are only a small number of replicated findings regarding the form or frequency of adjustment disorders among older patient groups. However, it has been amply clear that the currently employed 6-month time limit for adjustment disorders is inadequate when one faces a persisting stressful situation, such as a chronic physical disability or the need to care for a spouse with Alzheimer's disease.

While there were some minor text changes in DSM-IV regarding substance use disorders, there has continued to be relatively little attention to specific issues related to older persons. Recent studies[8] have underscored the variety of misconceptions that clinicians hold regarding the frequency and impact of alcohol-related clinical conditions. Many substance abuse problems among elders arise from misuse of prescribed medications; older patients often avoid the adverse social consequences of drug seeking and the medical complications of illicit intravenous administration. Although the abuse/misuse may be physically hazardous, especially as it relates to changes in metabolism or potentials for drug interactions, it is distinct from the jeopardy experienced by younger abusers. Thus, the diagnostic classification must attempt to take into consideration age- and culture-related variations, with an eye to dealing with unsupervised use as well as frank abuse.

Axis II

Consideration of personality factors and related clinical disorders has been hampered by minimal data. Although one may conjecture about the changing presentation of Axis II psychopathology across the age span, there have been remarkably few relevant, systematic studies[9]. Clinicians often recognize residual dysfunctional personality features in older, previously diagnosed patients who later fail to conform to stereotypic descriptions. There are no categories available for denoting such conditions. Similarly, there is no diagnosis of "emergent" personality disorder for describing those patients who, having suffered marginally impairing personality traits throughout their lives, evolve a frank disorder in old age. For example, such a classification would capture those who, having been supported or buffered by others, become dysfunctional following the death of a spouse or parent. This view stresses the setting-dependent nature of disordered personality. Overall, pre-DSM-IV discussions swerved away from issues related to personality and aging, leaving them to be resolved in future editions. It is clear, however, that the domain of personality dysfunction—even if not captured by current diagnostic categories—is a major component of the geriatric landscape[9], especially when considering problems such as depression in primary care settings[10,11] or suicide in elders[12].

Axis III

As noted previously, DSM-IV includes guidelines for assisting a clinician in discriminating between a primary Axis I disorder and a symptomatic disorder due to a condition diagnosed on Axis III. When there is an etiologic tie, the general medical disorder should be noted as part of the Axis I diagnosis (e.g. "mood disorder due to Alzheimer's disease"), in addition to its notation on Axis III. Despite the presence of guidelines, no rule can be used as an infallible aid to determine whether a condition is truly a manifestation of a fundamental medical disorder or is an unrelated idiopathic ("primary") presentation that occurs by coincidence in the presence of a medical condition that is not tied etiologically to the Axis I psychiatric disorder. Clinical judgment must prevail. Similarly, there are no means available for indicating the current clinical significance of co-morbid conditions, whether they contribute to the patient's overall disability, are confounds of possible treatments, or are merely incidental, coexisting disturbances that have no therapeutic impact or functional implications when considering the primary psychiatric syndromes.

Axis IV

As constituted in DSM-III-R, Axis IV was often unsuitable for use with elders. Its exemplars failed to account for many of the common problems or stresses of later life. Additionally, there was no method provided in the manual for defining the contribution of positive psychosocial factors that mitigated or diminished the contribution of stressors to the development of psychopathology. DSM-IV took another approach, defining what might be called "problem areas". This approach avoided the shortcomings of the previous scale, and included a variety of domains relevant to elders, but it too provided no room for an assessment of compensatory factors, in addition to its problem-definition focus. A psychosocially orientated scale (or set of scales) is necessary, one that reflects a broad conception that includes social supports, occupational and environmental resources, perceived quality of life, as well as stressors, both acute and chronic.

Axis V

Functional ratings may have substantial predictive validity when used with elders, but also have proved unreliable when not used carefully. Current use of Axis V requires an estimation of functional capabilities based upon psychopathology alone. Many commentators question whether one can reliably separate functional deficits due to psychiatric symptoms from those arising from co-morbid physical disorders, especially in elderly patients with multiple diseases. Presently available global functional health measures are psychometrically robust and are excellent predictors of subsequent morbidity and mortality in older patient samples. Two separate rating scales, one devoted to overall global functional capability/disability and a second devoted to severity

of psychopathology, would likely show greater utility and reliability than the current Axis V measure. While this approach was discussed for DSM-IV, it was not adopted as it was viewed as untested. Future consideration of how best to rate a patient's functional abilities will be an important issue for DSM-V.

In a similar vein, development of a cognitive rating scale within the overall diagnostic classification would have substantial clinical and heuristic value. Here, too, one confronts substantial controversy. Does the clinician attempt to rate absolute capability or to assess change (i.e. decline)? While a measure reflecting intellectual integrity or decline would assist when considering a wide variety of disorders (including dementia, mood disturbances and psychoses), how should one account for variations in literacy, education, cultural background or country of origin? At present, no single scale has proved suitable for all circumstances. Before inclusion in any formal diagnostic system, such a measure would require substantial testing to ensure both its validity and its reliability.

CONCLUSION

Geriatric psychiatry is only now achieving in the USA the attention and status that it has held for many years in other countries. Historically, clinicians and researchers who have worked in this area have had little impact on the nosologies recorded in the diagnostic manuals of the American Psychiatric Association. This situation is changing dramatically. However, specific suggestions for revision bear only as much weight as the strength of the research base upon which they are built. The rapid growth in North America of research dealing with psychopathology of the elderly is a heartening development, one portending future changes in DSM-V that we may not have yet anticipated.

History and Mental Status Examination

Hallie N. Richards[1] and Gabe J. Maletta[2]

[1]*University of Minnesota Medical School and* [2]*VA Medical Center, Minneapolis, MN, USA*

A successful psychiatric evaluation in the elderly, including a comprehensive mental status examination, involves integrating components of both medical and psychiatric clinical models. The classic medical model pursues symptoms and signs in a problem-orientated fashion, seeking to match them with a single unifying diagnosis and then designing an appropriate treatment strategy leading to a cure. This approach is less useful when dealing with geriatric patients. With these patients, aspects of the psychiatric clinical model are emphasized, i.e. ongoing treatment rather than cure, and chronic rather than acute care given by an interdisciplinary team. This strategy leads toward maximizing and maintaining individual function and behavior. Geriatric care is involved less with disease and more with disability. This is the case whether the patient has a psychiatric or general medical problem; and treatment goals must address the situation of chronic care needs, in contrast simply to the "fixing" of an isolated problem. Complicated presentations of disease in this age group create problems most successfully approached from an interdisciplinary perspective. Many syndromes manifest themselves with symptoms common to psychiatry, internal medicine and neurology, illustrating the overlap of these disciplines in geriatric care. The unique and challenging aspects of interviewing the elderly requires developing an individualized, functional clinical examination. With this goal in mind, the medical history will be examined and utilized to illustrate how the different medical specialties interact to integrate the art with the science of medicine. A successful blending will result in obtaining the most clinically useful examination possible.

PURPOSE

Obtaining a valid and reliable medical history continues to yield a correct diagnosis in over 80% of clinical situations[1]. This remains true in elderly patients, but accomplishing the task in this age group is often difficult and time-consuming. Perfecting the skills required to interview successfully an old, sick individual is invaluable in understanding an unusual disease process or avoiding costly mistakes in evaluation and treatment[2]. The working, hands-on abilities necessary to effect a successful history fall within two separate realms: fact-finding (science) and empathy (art)[3]. In the first realm, traditional medical training is replete with teaching and experiences. On the other hand, tutelage yielding artful practitioners is much less universal; indeed, it is becoming a rare and treasured experience in a medical residency.

With a view in mind toward expanding the "art" realm, a new look at interviewing elderly people is indicated. The interaction between patient and interviewer becomes much more than the process of collecting facts and related information to make a diagnosis. Gaining medical and social facts pertaining to the individual's problems is a primary but not exclusive goal. Older adults often come to the physician with a complex agenda that may not be obvious by dwelling only on the chief complaint. Conducting the interview by this conventional fact-finding method may not be productive and actually may put one at risk for generating too narrow a differential diagnosis.

In addition to laying the foundation for a satisfying therapeutic relationship, the initial gathering of information should guide the first steps in evaluation. Logical, stepwise investigation of symptoms and signs remains the practical approach to any medical work-up. If this investigation yields nothing, the urge to perform more elaborate tests should be resisted and one should return to the history. Greater dependence on reviewing the history again with the patient is more likely to yield an appropriate plan. The "law of parsimony" is not as useful a guiding principle in the care of geriatric patients as it is in general medicine[4]. A single, unifying diagnosis may not explain satisfactorily a symptom complex responsible for a precipitous functional decline in an elderly individual, and continuing investigation frequently uncovers multiple causes.

An understood but often unstated purpose of the medical interview with old people is getting to know the patient. This requires interviewer empathy (not sympathy or emotional involvement), which may be of the highest importance in the patient's view. Using the initial interview to explore personality and life experiences helps build rapport that is essential to subsequent interactions. Whether a patient's problem is psychiatric or medical, the initial interaction and relationship that grows from it are vital to achieving the goal of proper diagnosis and treatment.

ELEMENTS

Although the components of the medical history in geriatrics do not differ from those in the practice of any other specialty, the order in which they are pursued and their relative importance may be unique. The classic approach of taking a symptom-directed chief complaint, history of present illness, past medical history, review of systems, social history and family history will produce a desired database from which to work. However, mechanically and swiftly following an unbending order or sequence of impersonal questions may provoke successively less and less cooperation if the patient perceives that you are not really "listening". A more effective approach may require the physician to give up some control over the process of the interview, allowing the patient to

conduct it on his/her own terms. Valuable information that would otherwise be missed may be hidden in a conversational tangent the patient insists on following.

Review of previous medical records is necessary but they may not be available while you are seeing the patient. Especially in the elderly, a variety of information sources must be accessed in addition to the patient, including reliable family members and others in the social network. Indeed, if these other sources are lacking this should be noted and may itself have significance in the geriatric setting. Even in cognitively intact persons, corroboration is a good idea, as the "facts" may be related differently depending upon one's perspective. Non-medical problems, such as financial stress or social isolation, invariably impact on the elderly patient in unpredictable ways and cannot be ignored while investigating a medical complaint. After thorough investigation of each part of the history, the stories, details and facts are compiled, reviewed and evaluated, resulting in an in-depth, composite picture of the person in relation to the clinical issue at hand.

EXECUTION

For the older patient the first encounter with a physician is very important. Any subsequent interaction will be strongly influenced by the patient's initial impression, e.g. empathetic or distracted, rushed or friendly, interested or detached, confident or tentative. All things will flow from the stage set in the first few minutes of the interview. Therefore, serious thought should go into the initial 5 or 10 minutes of conversation. The physician must approach the situation with confidence, courtesy and the belief that some treatment plan can be developed, no matter how hopeless the situation may initially seem. Indeed, an optimistic stance is often useful when dealing with an elderly patient. The only thing on the physician's mind during the interview should be the patient and the problem at hand.

A skilled interviewer simultaneously questions, interacts (exchange of information), observes and, most importantly, listens. Proficient listening is an active exercise, requiring great concentration. Well placed periods of silence can be fruitful regarding observation or obtaining additional volunteered information, if the atmosphere is supportive and relaxed. It is not necessary to keep a dialogue going non-stop throughout the interview. Silence should be considered as a positive strategy. Sometimes, silent observation is extremely useful, especially with patients who seem to be actively hallucinating or exhibiting abnormal motor movements.

The examiner must function at many levels of interaction simultaneously, which can be physically draining. Making adjustments and modifications for the sensory and sometimes cognitive impairment extant in some patients adds to the interviewer's stress. These modifications include: sitting close; speaking slowly and loudly with frequent repetition; provision of ample time to allow for responses, which often have a prolonged latency; and even, when possible and necessary, use of sound amplifying devices[5].

More active engagement and even providing verbal direction may be a useful and effective tactic during the interview. The personal style of the interviewer is an individual but important trait, and the patient must be convinced that it is genuine. This occurs if the interviewer is truly interested and able to suspend any distracting thought or action. Physical expressions of concern, including touching (e.g. hand holding) are often appropriate with particular geriatric patients and helpful in reinforcing positive rapport.

The best initial tactic is to focus on the chief complaint, but not be limited by it. Know the planned questions and format of the entire interview well, allowing for rearrangement of sections during a particular interview to suit individual situations. This will allow a fluid order without interruption so that an interesting tangent may be followed easily. Open-ended questions may not be productive with the elderly, and if no progress is being made, asking focused, specific questions or using different, sometimes simpler, wording may succeed.

In spite of thoughtfully executed and patiently stated questions, contradictory answers may still be the end result. At that point resist a frustrated summary and probe further, pushing for elaboration. The contradiction will either be resolved directly with new information, or may itself provide new insight when it cannot be explained. Patience is required of both the examiner and patient, and it may be necessary to execute the complete interview in several parts, deferring some material to subsequent sessions.

Astute observation of the patient throughout the entire interaction may yield more information than a multitude of questions. The interviewer, acting as a receiver, uses all senses—eyes, ears and especially immediate feelings—to accept and interpret transmitted information. Much is learned by gazing in the face of an elderly person, e.g. presence or absence of eye contact, facial musculature, position of the head and general affect. Subtle body language, such as hand motion or lack of it, can suggest affective disorder, neurologic or medication problems, or perhaps substantiate complaints of arthritis.

Commenting on objects or memorabilia observed in the surrounding environment serves the dual purpose of providing the opportunity for light conversation and again for building rapport. Reminiscence of earlier times, when the patient was in greater control, can also be a valuable method of gathering data, in addition to putting the patient at ease and strengthening the therapeutic relationship. For the unusually quiet elderly person, try specific "ice-breakers", such as:

"Tell me the story that is your life . . ."

"What was it like to be alive when (some significant event) . . .?"

"When you were my age, how long did you think you would live?"

This particular tactic may even provide the interviewer with insight into cohort differences among different-aged elderly and their impact on disease presentation in individual elderly patients.

Certain problem situations present unique challenges when interviewing the elderly. Unavoidable physical limitations, such as fatigue, hearing or visual impairment and chronic pain, may limit the time of the interview itself or influence the amount of information gained. Cognitive problems, such as memory loss or inability to pay attention, and psychiatric illnesses (temporary or permanent), such as dementia, delirium, generalized anxiety, major affective disorder or even psychosis, may cause difficulties and such diagnoses may only become apparent well into the interview, making all information obtained up to that point suspect. Also, patient biases of many types, such as racial, language and cultural, need to be acknowledged to avoid misinformation and miscommunication. Old patients may view young physicians with distrust, just as age bias may occur in the opposite direction.

Closing the interview successfully is as important in overall impact as is the initial impression[6]. Take care to ensure that all issues on the patient's agenda have been addressed. In any event, a useful strategy is always to end the interview by asking the patient if there are any questions he/she would like to ask the interviewer. Key questions may often be asked by the patient just as the physician closes the encounter, uncovering hidden fears or revealing the real reason (not the stated one) for the visit. Adequate time for patient questions, empathetic listening and thoughtful responses often yield insights missed or left unexplained earlier. A brief statement to the patient at the end of the

interview about "where to go from here" can instill confidence that something will be done soon. Later, after time for thoughtful consideration, a detailed explanation of the assessment and treatment plan can be discussed with all interested parties.

The primary goals of psychiatric and general medical treatment merge in the elderly patient[5]. They include the amelioration of symptoms, restoration or maintenance of optimum function, and enhancement of the subjective quality of life. Since curing the elderly of disease is usually not possible, focusing on these goals in a caring manner will enhance the physician–patient relationship and increase the chance of success in treatment.

Once the facts are gathered, one then needs to spend considerable time systematically reviewing and organizing the data into meaningful information, i.e. the formulation. This allows for the development of an integrated diagnosis and treatment plan. The plan is a framework and remains a guide, but can be altered depending on subsequent events and the patient's response to therapy. A well thought out plan also helps avoid costly and often fruitless searching and testing that may lead to over-diagnosis and risky therapeutic choices. Both professional and personal rewards result when extra time and effort are invested in thoroughly examining an elderly person in this manner.

MENTAL STATUS EXAMINATION

The formal mental status examination (MSE) is obtained once a thorough history is obtained. It is a measure of both general psychiatric status and specific cognitive function or dysfunction. Equal time, patience and concentration are required for this portion of the interview, and, especially in the mentally ill elderly, often is a more difficult task for the interviewer. This is because the MSE touches on areas and experiences that may be uncomfortable, embarrassing or even frightening for the patient. Often, parts of the MSE will have already been satisfied by previous observation and interaction while taking the history, e.g. level of consciousness, appearance and behavior, affect, and parts of the sensorium examination (attention, word-finding).

Table 24.1 displays the components of a formal MSE in the psychiatric interview. The patient's level of consciousness should be described at the outset. Columns 1–4 of Table 24.1 are examples of common descriptors illustrating possible presentations of mental illness. The last four columns suggest areas to consider when investigating sensorium, judgement, insight and risk of causing harm.

At the conclusion of the MSE all acquired information can be recorded in a comprehensive psychiatric database, as outlined below. This serves many purposes, but most importantly it encourages systematic review, comparison with subsequent examinations, and decreases the possibility of overlooking details important to a correct diagnosis. Formulation of an individualized assessment and treatment plan, including functional status, completes the process and, once recorded, allows review and revision at any time. It should be reinforced that psychiatric evaluation of the geriatric patient, including history and MSE, although similar in some ways to examination of younger patients, differs in some key ways. The most important, unique difference for the examiner to understand and appreciate is the need to integrate into the MSE the assessment of concomitant chronic and acute medical conditions and also to augment the historical data obtained from the patient by interviewing other reliable individuals with pertinent information.

Database History

Identification
Informant(s)—determining reliability of the historian is important. It is often useful to supplement the interview by meeting and questioning family and/or friends

Disciplines other than psychiatry routinely test only orientation to satisfy this section of the MSE. It is important to perform a standard, valid and reliable cognitive examination to achieve an acceptably comprehensive MSE. The Mini-Mental State Examination (MMSE) is a good example of an acceptable test[8]. Also, besides testing cognition, other instruments may be useful in particular patients, especially to evaluate mood and functional capabilities[9]. The interviewer should become familiar and experienced with one or two scales in each area, e.g. Geriatric Depression Scale[10] or Beck's Depression Inventory[11]; Activities of Daily Living[12] Instrumental Activities of Daily Living[13]; Global Deterioration Scale[14]; Cognitive Performance Test[16] Global Assessment of Functioning[17].

The Physician's Role

Lesley Young

The idea that mental disorders may be the result of bodily disease acting on the brain has been current for at least a millennium, since the time of Avicenna[1]. Numerous attempts to relate specific psychological reactions to particular physical disorders have been unsuccessful, however, and it now seems clear that some general mechanism affecting the chemical environment of the brain is responsible[2]. Many descriptive classifications of "organic psychosis" have had to be abandoned and not even the notion of "clouding of consciousness" has always been regarded as a cardinal feature of delirium[3], although the most recent definition of delirium includes "disturbance of consciousness with reduced ability to focus, shift or sustain attention" as a diagnostic criterion[4].

The clinician dealing with a mentally disturbed patient must consider any process capable of interfering with cerebral metabolism or neurotransmission[5,8] as a possible causal factor. Moreover, for reasons still not well understood, the probability of a mental disorder arising from a "physical" cause is greatly increased in old age, so that the psychiatrist will rarely see a mentally ill old person without significant physical disease[6] (and the geriatrician must likewise develop expertise in psychiatry).

The aim of the physician when confronted with a mentally ill patient should be to answer two questions:

- Could there be a physical cause for the mental disturbance?
- Is there any physical condition that is making things worse?

DELIRIUM

"Acute confusional states" are common in old people[7], indeed it is claimed that mental confusion is a far more common herald of physical illness than pain, fever or tachycardias[8]. Delirium may also go unrecognized by attending clinicians[9], or be misdiagnosed as dementia or depression[10], with potentially disastrous consequences[11]. Not only may this mean a denial of personal rights or even permanent incarceration in an institution, but also the underlying cause may go undetected and therefore untreated. Although detailed mental state examination and formal cognitive testing may give some clues, delirium and dementia can only reliably be distinguished by obtaining a full collateral history and by observation of the subsequent course of the illness. However, the serial use of cognitive screening tests, such as the Abbreviated Mental Test score[12] or Mini-Mental State Examination[13], has been shown to be useful in helping to distinguish delirium from dementia. Disorders of attention and alertness are prominent features of delirium, and tests of reaction time and the "face/hand"[14] tests have been claimed to distinguish those whose mental disorder is of recent and rapid onset. Hallucinations and other perceptual disorders are also common and may be found in the absence of any other apparent mental illness, so such phenomena may be under-reported for obvious reasons. Visual hallucinations are said to be particularly common following bereavement[15] and isolated perceptual disorders such as the Charles Bonnet syndrome[16] may be associated with pathology of the sensory system involved, although such phenomena are also seen in cerebrovascular disease[17]. None of these features is unique to delirium, however, and the only reliable way to distinguish delirium from dementia, and sometimes from functional mental illness, is to obtain a detailed history from a third party: the most useful diagnostic tool is the telephone.

If in doubt it should be assumed that the mental disturbance is acute and therefore potentially reversible, so a physical cause should always be sought, a process that may require some detective work. Appropriately enough, the first step is to suspect that the victim has been poisoned. A full drug history, including both prescribed and over-the-counter medication, is necessary. Although drugs acting primarily on the central nervous system, and particularly those affecting the cholinergic neurotransmitter systems, are the most likely to cause problems, any medication should come under suspicion. Numerous drugs have been shown to have cholinergic effects, including many drugs that would not initially appear to exert such an action[18]. Polypharmacy is common in older people[27] and relatively minor cholinergic effects of each individual drug may exert a cumulative effect, thus, the delirium may not be due to one individual drug but rather the combined effect of several. Drugs affecting cardiac output or cerebral blood flow may precipitate memory changes, and diuretics also produce a range of adverse metabolic effects of their own. Long-term use of laxatives may have similar effects. "Minor tranquillizers", such as the benzodiazepines, once thought of as safe alternatives to the barbiturates, are now recognized to cause acute psychiatric disturbance[19] as well as chronic mental impairment, unsteadiness and falls[20]. Opiates, often prescribed together with mild analgesics in combinations such as co-proxamol, may cause acute or long-term problems.

Long-term use of addictive drugs is surprisingly common in the elderly population[21] and is often the result of careless prescription of sleeping tablets or painkillers. Alcoholism is probably an under-recognized problem[27,23] and in this context it should be remembered that delirium may just as easily result from sudden withdrawal of long-term drugs as from their use[24].

Examination of the patient often begins with inspection of the home, looking particularly for evidence of drug or alcohol abuse, poor diet, incontinence and general signs of short- or long-term neglect. The family and neighbours should be interviewed

wherever possible, mainly to establish the patient's normal mental and physical state and the timing of any change, making use of "landmarks" (such as Christmas) to focus the memory. The patient's current mental state should then be assessed in the light of this information.

Diagnosis and Assessment

When assessing an elderly person with a potential delirium, it is useful to bear in mind the common causes for precipitating delirium, which include infections, biochemical and metabolic derangements, organ failure and drugs. There is frequently more than one potential cause and thus assessment should be continued, even after one "cause" has been identified.

The approach and manner of the clinician towards the patient are of great importance. The aim is to provide a stable and, if possible, familiar sensory environment, so assessment should take place in a well-lit room with a minimum of distracting and misinterpretable stimuli. Physical examination starts with assessment of general hygiene, nutritional state, hydration and superficial signs of injury.

Body temperature must be measured with care: significant infections usually cause fever at any age[25], although it is often missed in elderly patients, where oral or axillary temperature may take longer to equilibrate with core temperature[26]. Suspected hypothermia must be checked by measuring rectal temperature. The relationship between peripheral and core temperature depends mainly on the state of the circulation: cool peripheries are just as likely to indicate arterial shut-down, due to low cardiac output or hypovolaemia, as hypothermia. Other important signs of dehydration or blood loss are a low jugular venous pressure (venous pulsation not visible at the root of the neck with the patient lying at 20° or less to the horizontal) or postural hypotension (a fall of over 20 mmHg systolic and/or 10 mmHg diastolic on sitting or standing up). The latter may, of course, be due to the effect of drugs or autonomic failure, in which case the fall in blood pressure may not be accompanied by reflex tachycardia. High blood pressure has little diagnostic value and should normally be left alone in the acute situation.

Abnormalities of heart rate or rhythm can also seriously affect cardiac output and cerebral perfusion. Heart rate should be assessed by both feeling the pulse and listening over the precordium, where murmurs can also be detected. An electrocardiogram is an essential extension of clinical examination and, as well as documenting heart rhythm, may also show clinically undetectable signs of myocardial infarction. Signs of cardiac failure should be sought, including the presence of a gallop rhythm, fine inspiratory crepitations in the chest and peripheral oedema. The peripheral pulses should be felt. Bruits in the neck are useful, although non-specific, markers of arterial disease.

Abnormalities of respiratory rate or pattern must be noted, as well as the presence of central or peripheral cyanosis. In a delirious patient with cyanosis, warm peripheries and bounding pulses, the characteristic flapping tremor of CO_2 retention should be sought. Focal signs in the chest are useful but non-specific, and a chest X-ray is nearly always required. Any sputum must be examined at the bedside as well as sent for microscopy and culture. Arterial blood gasses are sometimes useful, but both persistent and transient hypoxaemia can be detected non-invasively with a pulse oximeter, although in the presence of signs of hypercapnia measurement of arterial blood gases is preferable.

Examination of the alimentary system begins with nutritional assessment and inspection of the mouth, looking for evidence of sepsis or neoplasm. The abdomen must be carefully examined, as virtually any surgical emergency can present as a change in mental state without apparent abdominal symptoms. Abdominal signs may be far from obvious and many a strangulated hernia in an elderly patient has been missed by the unwary.

Urinary retention and faecal impaction are often detectable per abdomen but a rectal examination should also be done wherever possible. Whether constipation can cause delirium by itself is still a subject of vigorous debate, but most geriatricians and general surgeons are familiar with the elderly patient whose mental and physical state improves dramatically with rehydration and enemas. Examination of the perineum includes inspection of clothing for evidence of incontinence or precautions against it. Incontinence is a frequent finding in patients with delirium[21]; whether as a consequence of the underlying cause or as a direct result of the mental disturbance is not clear.

In the locomotor system, trauma and acute inflammation are important causes of delirium and swelling, warmth, tenderness and pain on movement of any joint should give rise to suspicion. The feet should be carefully examined for signs of ischaemia or sores, and the gait observed.

The most important part of neurological examination is the assessment of conscious level and higher mental function. In a delirious patient this is as much the province of the physician as the psychiatrist and it is important that both terminology and assessment should be standardized. The hard-pressed house physician confronted with an acutely disturbed patient in the middle of the night is unlikely to turn to the Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Association for immediate guidance, but she might find a simple standardized assessment of attention, orientation and memory, such as the 10-question Abbreviated Mental Test Score[28] or the Mini-Mental State Examination[13] useful. Such tests are often criticized because they are prone to misuse, a low score being taken as evidence of dementia, but their main value lies in repeated use, when dramatic changes often seen in acute medical patients clearly point[29] to delirium rather than dementia as the cause of poor performance. The routine use of such tests reminds the busy junior doctor to consider the possibility of delirium, and may prompt a search for the underlying cause in those who have a low score. Moreover, routine use of cognitive screening tests can avoid the clinician being fooled by an apparently cognitively intact older person who, in fact, has a significant cognitive deficit but a good "social front", can act as a baseline should the mental status change. It is important to be aware, however, that these tests are merely screening tests, and the scores are influenced by numerous factors other than the current mental disturbance. Including sensory impairments, educational level, social class and language. When applying standardized criteria to patients admitted to a geriatric assessment unit, 18% satisfied DSM-III-R criteria for delirium on admission[29] and the mean duration of the delirium by the same criteria was 7 days. Some deficits persisted longer, however, notably memory impairment, with a mean duration of 28 days. The use of standardized scales will not replace clinical judgement but will undoubtedly lead to greater clarity of thought and discussion, and is essential for progress in research.

Many clinicians place great emphasis on careful neurological examination, looking for focal signs which, if found are usually attributed to cerebrovascular disease. This assumption may often be correct, although the evidence is scant, but it is a mistake to blame everything on acute stroke, since the metabolic disturbance causing delirium may simply be highlighting areas of brain ischaemia. Thus, focal signs may be related to previous stroke damage, where neurological function has largely recovered although perfusion has remained impaired. If this is not appreciated, then the real culprit, which might be a treatable infection, may be missed.

The reliability of subtle focal signs, such as asymmetry in tendon reflexes, should also be regarded with scepticism, given the extent of inter-observer variation in the assessment of the patient with obvious hemiplegic stroke[30,31]. The most reliable signs are those that can be easily reproduced and particularly those that are reflected in the patient's behaviour, such as dysphasia or unilateral neglect. This raises the more general point that the diagnostic assessment does not end with the formal physical examination but must include careful observation of the patient over the next few days. A host of signs that might otherwise have been missed, from episodes of fever, syncope, or fits to a craving for alcohol or opiates, may be revealed. Assessment of vision and hearing are particularly important, as the presence of sensory deficits may increase the risk of developing delirium, and a recent study showed that attention to and correction of sensory deficits may reduce the severity and duration of delirium[32]. Impairments of vision or hearing may also only become clear after a period of observation.

The choice of laboratory tests tends to be determined more by institutional tradition and by habits and attitudes of the clinician than by scientific evidence. The value of any tests depends largely on the prior probability of finding treatable disease. Thus, the urine should always be tested but a computed tomography (CT) scan comes low on the list of priorities. Whilst CT head scans may frequently show minor abnormalities, such as cerebral atrophy, a cause for delirium is rarely found unless there are other features in the history and examination to point to an intracerebral cause, such as new onset of focal neurological signs[33]. Similarly, whilst electroencephalography (EEG) is frequently abnormal in delirium, showing diffuse slow-wave activity[34–36], it is rarely useful as a diagnostic tool unless there is clinical suspicion of epilepsy. Indeed, the very non-specific nature of the EEG changes seen in delirium raises interesting (although under-researched) questions about the pathogenesis of the disorder. Other invasive tests, such as lumbar puncture (LP), have been used in research and numerous abnormalities of neurotransmitters have been identified in delirium, but as a diagnostic test in clinical circumstances, LP is again only useful in those with features of meningism[37,38].

The range of diagnostic possibilities is almost always wide and there may be few clinical clues. This has led to the erroneous and derogatory use of the expression "geriatric screening" to describe the laboratory investigation of elderly patients presenting with non-specific symptoms or functional problems. Screening tests always have a low yield, since the vast majority of subjects have nothing wrong with them, whereas tests done in order to track down the cause of delirium have a high probability of showing an abnormality, and serum calcium, urea and electrolytes, full blood count and glucose should virtually always be done.

DEMENTIA

Delirium and dementia commonly occur together; indeed, the pre-existence of dementia is a major risk factor for the development of delirium[39] and up to 70% of patients presenting with an episode of delirium will have some degree of chronic brain failure as well[40]. There is a clear relationship between the degree of vulnerability of a patient and the size of the insult required to precipitate delirium[39]. The principles of assessing a patient with "decompensated dementia" are similar to those outlined above, with some slight changes in emphasis. A psychological upset or disruption of the normal protective social environment may be enough to precipitate a crisis in a mentally frail person. Whether or not such an episode of decompensation actually constitutes delirium is debatable[41] but it can only be a short step away, as physical complication such as exhaustion, dehydration or hypothermia may quickly supervene. Whether or not the initial event was some kind of social or psychological trauma, it should not prevent a careful search for physical disease, for in such frail individuals, relatively minor remediable disorders can have dramatic functional consequences.

The distinction between decompensated dementia and delirium is also of practical importance because of the special problems involved in admitting the former group to hospital. A balance must be struck between the patient's need for a stable, familiar and reassuring environment and the availability of facilities for investigation and treatment. The former may be the overriding consideration in the case of decompensated dementia, while in the previously well person with delirium the latter is the main concern. In some (but not all) cases, day hospital facilities may provide a useful compromise.

Physical illness in a person with dementia may also present a decline in physical rather than mental function, with development of non-specific symptoms or signs such as unsteadiness, falls, immobility or incontinence. Again, the sudden appearance of such problems should not be assumed to be due to the progression of dementia or put down to "another stroke" but must be investigated, since timely intervention may prevent irreversible deterioration or even unnecessary institutionalization.

Recent research has highlighted the associations between physical illness and dementia, particularly vascular pathology and risk factors for such conditions. Dementia is thus significantly associated with the presence of atrial fibrillation[42], ischaemic heart disease[43,44], cerebrovascular disease[43,44], hypertension[44,45] and diabetes[46,47]. Moreover, there is suggestive evidence that poor control in some of these conditions may result in accelerated cognitive decline[45]. Therefore, whilst evidence from large-scale prospective studies is not yet available, it would seem sensible for the physician to actively treat such coexisting physical illness in the presence of dementia. Whilst high blood pressure appears to be a risk factor for the development of dementia, the prevalence of low blood pressure and orthostatic hypotension (OH) is also more common in dementia and may have an aetiological role[48,49], and the physician should be alert to the presence of OH and consider appropriate intervention.

Involving physicians in the assessment of patients with dementia is important to help rule out a treatable cause. Clearly no-one can afford to miss "reversible dementia" but unfortunately we have no idea of its true prevalence. Estimates of the frequency of reversibility in series of hospital patients has been reported to be as high as 40%[50], but older studies are hopelessly biased by concentrating on younger "pre-senile" patients from secondary or tertiary referral centres. In the few community-based studies that have been reported, the frequency of "reversible" cases was less than 10%[51]. More recent studies have estimated the prevalence of potentially reversible dementia in the region of 7.2%[52] to 23%[53], although only at best 3% were actually reversed[52,53]. An analogy may be drawn with the frequency of space-occupying lesions in patients presenting with "acute stroke", which was estimated at 15% in a study based at a neurological centre[54], compared to 1.5% in a series of patients admitted to an acute geriatric unit[55] and a similar figure in a community stroke survey[56]. There is an urgent need for equivalent community-based studies of dementia in which all cases are thoroughly investigated. Until then, practice must be based on questionable and possibly ageist assumptions about the likelihood of finding treatable disease in particular groups of patients. Thus, few clinicians would disagree that younger patients should be fully investigated, as well as those of any age whose symptoms are of recent onset or rapidly progressing.

As emphasized above, a careful drug history is of overriding importance, since it is bad enough to miss a treatable disorder but unforgivable to be responsible for causing it or making it worse. As in the case of delirium, all drugs should come under suspicion,

including some superficially unlikely offenders such as digoxin, non-steroidal anti-inflammatories and cimetidine. The anti-cholinergic effects of phenothiazines, tricyclic antidepressants and anti-Parkinsonism drugs commonly cause problems. Longer-acting sulphonylureas may produce a state of chronic befuddlement in elderly patients, contrasting with the acute hypoglycaemic episodes and prominent adrenergic symptoms usually seen in younger diabetics. Stomach remedies, laxatives and diuretics may bring about mental changes through electrolyte disturbances and other mechanisms.

Physical examination is rarely helpful if the patient is ''well'' but localized neurological signs should obviously raise suspicions of a space-occupying lesion. The association of incontinence and ataxia or gait apraxia with mental disturbance may suggest normal pressure hydrocephalus, but there is considerable overlap with cerebrovascular disease[51]. Similarly, signs of Parkinsonism may be observed in patients with multi-infarct disease or diffuse Lewy body disease, who are unlikely to benefit much from L-dopa. On the other hand, patients with the characteristic extended posture and vertical gaze failure of progressive supranuclear palsy may respond to high doses of dopamine agonists[58]. If the mental deterioration was preceded by a fall or there is evidence of head trauma, no matter how minor, suspicion of subdural haematoma should be aroused.

Some investigations, such as serum B_{12} folate, calcium, thyroid function and screening for syphilis, are cheap to perform and lead to simple, if not always effective, medical treatment if an abnormality is found. It should be remembered that neuropsychiatric disorders caused by cobalamin deficiency[59] or folate deficiency[60,61] can occur in the absence of haematological changes. On the other hand, the scientific evidence on which to base an effective and economically realistic policy for the use of expensive brain imaging techniques in people with dementia is still lacking.

Since the ''treatable syndrome'' of normal pressure hydrocephalus was first described by Adams *et al.*[62] in 1965, there has been little agreement about the precise definition of the condition or the indications for treatment. Ventricular enlargement, with or without periventricular leukoaraiosis and various degrees of cortical atrophy, is a common CT finding in mentally normal old people, as well as those with dementia and other neuropsychiatric abnormalities. Clearly, it is not practical to monitor CSF pressure or to perform a lumbar infusion test in all cases, especially as such investigations do not always predict the response to internal shunting[63]. Common sense would suggest that the response to repeated removal of CSF by lumbar puncture might be the best predictor of long-term benefit from surgery, but there again no systematic prospective study, let alone a randomized controlled trial, seems to have been done.

Similar, although less profound, uncertainty surrounds the treatment of subdural haematoma in the elderly. Here at least the CT scan should show a definite abnormality, but the relative merits of surgical and medical treatment (or none at all) are not precisely known. At the time of writing it is not possible to make logical recommendations for the clinical assessment and investigation of elderly people with dementia, since the issues are still surrounded by a fog of confusion and prejudice. The costs of investigation for all may be high, but they must be weighed against the enormous costs of institutional care and the psychological, social and indirect costs of the burden on carers, a substantial part of which might be avoidable. Large-scale, pragmatic outcome trials are urgently needed.

Depression and Functional Illness

In operational terms, if not according to strict definition, the commonest of the reversible dementias is so-called ''depressive pseudo-dementia''. Here the psychiatrist has more to offer, but the physician is often involved because of the frequency of somatic symptoms and physical disabilities manifested by elderly depressed people. Indeed, when neither physicians nor psychiatrists are involved, people with potentially treatable illness can become heavy consumers of social services[64] or even residential care[65]. In this situation the psychiatric history and mental state examination are of paramount importance, although yet again the possibility of adverse drug effects must be borne in mind. β-Blockers, methyldopa and benzodiazepine are often implicated[66]. Alcohol may be a cause or contributory factor and a simple screening questionnaire, such as the CAGE, should be included in any medical or psychiatric assessment[67]. Physical examination is likely to be less rewarding. Although depression is a common complication of many physical illnesses, the proportion of cases where it is the sole presenting feature is quite small. Nevertheless, the chances of finding physical disease in elderly depressed patients are far higher than in their younger counterparts and its presence has a substantial adverse effect on prognosis: indeed, severe intractable depression in old age is nearly always associated with chronic physical ill-health[68]. Secondary complications of depression, such as dehydration, nutritional deficiencies and constipation, must be identified and treated. It is unlikely that metabolic disturbances such as diabetes or hypothyroidism will be diagnosed clinically, so the appropriate blood tests should be done in all cases. A high ESR or C-reactive protein level should warn of the possibility of tuberculosis, other infection or cancer. An intensive search for occult neoplasia is rarely justified, although a chest X-ray should be done in any patient whose symptoms do not respond rapidly to treatment. Once again, the role of CT scanning will remain unclear until prospective studies of representative groups of old people presenting with clearly defined psycho-syndromes have been reported. Finally, it should be remembered that the goal of clinical assessment in elderly patients is rarely to make a single unifying diagnosis. Multiple pathology is the rule rather than the exception and unusual combinations of symptoms or signs are more likely to be due to the combined effects of several common diseases rather than one rare one. The reduced homeostatic reserves of old age also means that a single initial insult (or treatment) often begins a chain of metabolic disturbances that multiply, leading to a cascade of complications. Thus, whatever the primary event, the clinician is often faced with a range of problems as well as pathophysiological diagnoses. Mental disturbance may therefore be seen as just one aspect of a complex multi-system disorder, but few would dispute that it is one of the most interesting and challenging of all.

Needs and Problems

Barry J. Gurland

Columbia University Stroud Centre, New York, NY, USA

Reliable and valid assessment techniques are needed for precision in studying, and communicating about, mental health problems. "Assessment" in this context conventionally refers to questionnaires and performance tests and behavioural observations can also be a part of a mental assessment[1–7].

The content of assessment is usually derived from a clinical experience[8]. However, clinicians may differ from each other, or from one interview to another, in the manner of their interview and their interpretation of the patient's responses. Therefore, reliability in assessment is obtained, in part, by prescribing the order and form of questions and tests (structuring the stimulus) and defining the informative response to be rated (structuring the response)[9]. This structuring of the interview technique enhances reliability, while retaining the focus of a clinically administered interview.

Structuring of mental assessment comes into its own when the condition has to be described in fairly subtle or phenomenological or behavioural terms, or when outcomes are influenced only to a limited degree by treatment or other factors, or where alternative treatments are not obviously different in their benefit and costs. Dramatic outcomes involving, for example, the difference between life and death, or the full recovery of an unusually incurable condition, hardly require precise measurements.

In an effort to reach precision in assessment through structuring of interview, construct validity may suffer. Conditions that are the focus of clinical concern but that cannot be precisely measured by state-of-the-art techniques may be excluded from research attention. Researchers may also choose to select types of patients not posing a problem for measurement. Alternatively, the concept of the condition may be constricted so that it fits within a measurable entity[10]. As the scope of psychiatric treatment expands, assessment techniques may have to follow suit.

A large proportion of elderly patients in institutional settings, and of patients with conditions such as dementia, or long-stay ageing schizophrenics in institutions, are unable to communicate at even a simple level. Testing or performance on cognitive tasks may not be possible, and questioning about inner feelings and thought processes is often completely out of reach. Attempts have been made to address these assessment problems by resort to informants[11,12], observations of reactions to non-verbal stimuli[13] and inferences from responses to fairly straightforward stimuli, such as greeting behaviour. These approaches have not yet been proved to be entirely satisfactory.

The high correlation between mental and physical problems of the elderly makes it inevitable that mental assessment will often be confounded by physical symptoms. Somatic symptoms due to physical illness may register on scales intended to pick up the somatic manifestations of depression. Functional impairment due to physical infirmity[14,15] may spuriously fit criteria for determining the severity of dementia.

Various solutions to the confounding of the mental and physical symptoms have been proposed. Some investigators have chosen to develop instruments that concentrate on the mood state in depression[16,17] or the cognitive state in dementia[18], avoiding the need to attribute somatic or functional symptoms to a mental or physical cause. Other investigators have focused attention on the characteristics of somatic and functional symptoms that are suggestive of a mental rather than physical condition. Nevertheless, the measurement of the physical aspects of mental illness in the elderly still lacks specificity.

Potential users of mental assessment techniques are always concerned about the length of the time taken to administer the interview. Shorter interviews[19–22] are viewed as more acceptable to subjects and less likely to be prematurely terminated, leading to a higher response rate for repeat interviews, cheaper to administer and less prone to error. There is no firm evidence that any of these assertions are true. Brevity has been carried perhaps to an extreme in assessments that serve as screening tools in busy clinical sites. Moreover, little attention has been given to devising interviews that are engrossing, reassuring and even helpful to the subject, so that longer interviews would be welcome.

Lengthening the time available for completing an interview allows more information to be collected on mental health and its associations. For most purposes in research and in clinical applications, there appears never to be enough time for all that might be relevant to study mental illness or clinical management. Brief scales of single dimensions (e.g. depressed mood or cognitive impairment) generally consume up to 10 min of interview time. Inclusion of material bearing upon differential diagnosis[23–25] may extend to 30–40 min for current status and another 30 min or more for history of the illness. A comprehensive assessment[9,25], which covers the possible determinants and consequences of mental illness, may itself require 1 h or more, without exhaustive inquiry into any domain.

Compromises are usually necessary to keep the interview within feasible time limits while maintaining an adequate range of information. In this direction, contingencies may be introduced into the instructions for administration of the interview. Specified areas are probed only if a header question reveals the likelihood of useful information emerging from that area[26]. There is a remarkable absence of empirical data showing that the rationale for these contingencies is well based. Furthermore, the complexity of contingencies may trap the interviewer to errors. Nevertheless, these contingent decision trees do represent the best chance of replicating the efficiencies and productivity of the way an experienced clinician conducts an interview. The advent of

computer-assisted technology for governing the conduct of interviews should facilitate the management of elaborate contingencies for driving the interview.

A certain line of questioning or testing may hinge upon a large body of information already gathered, rather than a single item or short set of items. A classic example is the use of an interview as a screen to select subjects for further investigation. Typically the latter investigation is at a separate time and venue, but it could follow straight on the heels of the screening interview at the same session. In either event it is essential to have immediate analysis of the information determining the contingency. Simple additive scoring systems are mainly invoked in these circumstances. Computer methods now allow much more elaborate analyses to determine the flow of sequential interviews or even sequences within a single session interview.

The capacity for rapid retrieval of assessment information on demand greatly enhances the value of mental assessment for supporting clinical decisions. Yet the potential in this respect cannot be fully realized until clinical goals of assessment assume priority over research goals in shaping the form and content of the assessment. Notwithstanding that mental assessment emerged from clinical experience, the current state or nature of mental assessment owes much more to research than clinical interests. A return to the origins of its development is called for, in order to bring assessment into line with clinical as well as research needs[27,28].

Clinical activities, for reasons of practice organization and fiscal considerations, generally take place under pressure of time. The collection and even analysis of information for the review clinician can be delegated to personnel under less time pressure than the physician/psychiatrist. In that arrangement, it becomes essential that the transfer of crucial information to the physician be managed expeditiously. This entails highly discriminating summarization, display and communication of mental assessment information. It also assumes that the physician learns to assimilate the type and form of information and to incorporate it in the planning and monitoring of clinical management. This learning process, like other clinical skills, must be continuously honed through experience assisted by consultation. There are few guidelines as yet as to the assignment, conduct and necessary training for the professional role of marshalling the mental assessment information and communicating it to clinicians.

Much of mental assessment is aimed at documenting the subjective experience or inner states of a patient[29]. The best reporter for this material should be the patient, but the latter may be uncommunicative or give misleading information. An informant may not do much better. Under these circumstances, it would be desirable to turn to objective testing and observation of behaviour[30–32] and laboratory results if these can be obtained. As matters stand, laboratory findings in themselves are at best ambiguous[33] as mental assessment information in the elderly, although there is hope that eventually laboratory tests will play a larger part in mental assessment. In any event, whether intended or not, many subjects in epidemiological studies will not undergo laboratory testing. In the meantime, other ways of achieving objectivity are more likely to be productive. Testing organic mental status is objective in the sense that the task performance of the person is observable and errors can be quantified. Programming is the presentation of the tests through computer software and adds to the objectivity[13,34]. Testing of an objective nature has also evolved for functional performance for tasks involving everyday activities, or simulations of the skill demands entailed in such activities[14,15]. Inefficiencies in carrying out these tasks provide information on the diagnosis of certain mental conditions (e.g. dementia) and the outcomes of a wide range of mental illnesses.

Structuring of testing procedures (backed up by suitable training) allows the results of assessment to be compared with data collected on the same instruments in different studies. It also permits data to be interpreted in the light of accumulated experience on the normal distribution and longitudinal course of levels or patterns of test results in the general population and in specific clinically defined groups. Thus, the value of assessment information is enhanced in diagnoses, prediction of outcomes, selection of treatment and evaluating the significance of changes in levels or patterns of test scores. This full psychometric development warrants the use of the term "standardized" to describe a method (although the term is used to mean structured). However, there are several cautions that must be addressed in attempting to draw upon the potential value of standardization.

Unless an assessment technique is administered in identical fashion in two or more studies, the results of those studies cannot be directly compared and information cannot be transferred from one study to another. Not only must the structure and procedures of the assessment protocol be kept constant, but also the methods of training. Furthermore, adjustments must be made for differences in the characteristics (e.g. age, education and culture) of two populations that might alter the meaning and confound the comparison of results from the same assessment technique[35]. These adjustments may be difficult to make unless standardization has been accomplished on appropriate populations and formulae for interpreting scores have been worked out[36,37]. Attempts are being made to construct culture-free assessments which, in effect, would obviate the need to adjust scores with reference to demographic characteristics.

Most assessment techniques devoted to the classification of mental disorders still rely heavily upon information gathered at one point in time[38], cross-sectional status with or without retrospective historical information. Longitudinal or prospective information is principally regarded as measuring change, course and outcomes. Yet the longitudinal picture of mental health problems offers crucial clues to diagnosis and needs to be incorporated into assessment techniques for classification. In order to meet the demands of longitudinal measurements, assessment techniques must deal with practice effects, ceiling and floor limits to the range of measurement, and the minimization of attrition by maintaining the interest of the subject.

Certain domains of mental ill-health appear well-represented, even over-represented, in current assessment techniques. For instance, there are probably more measures of cognitive impairment[19,25,39–47] and of depressed mood[16,17,48–56] than are strictly needed. Conversely, there are neglected domains. Innovations would be welcome in the measurement of positive mental health, either as a global concept or as applied to specific mental health areas, such as affect[57] and cognition. There is a need to understand the contribution of the measurements of positive states to diagnosis and prognosis.

More generally, the scope of assessment techniques should be expanded and explored so as to fill in gaps in the domains relevant to describing mental health and its associations. Moreover, assessments need to encompass the various perspectives of subject, family member[11,12,58,59], health professional and other parties with a legitimate interest in the subject's mental health. When a complete inventory of domains and perspectives has been captured by assessment techniques, it may become possible to describe a reasonable approximation to the plight of the whole person.

A note on quality of life assessment. The concept and measurement of quality of life has come to fill a prominent place in geriatric health care. Since about 1970 the relevant professional literature on measurement and its applications has steadily increased in volume. Instruments have proliferated and some have assumed ascendancy in terms of widespread use. There is no better indication of the need for measurement of this concept than the many applications to which it has been turned. These

include descriptions of the course of illness, comparisons of the outcomes of competing treatments, monitoring of the performance of healthcare systems, accounting for benefits derived from resources allocated to various interventions, assisting decisions on treatment choice, and informing policy formation on development of the health care system and its components.

Yet there are problems of concept and measurement that have emerged for which no satisfactory solutions have yet been found. For example, there are unresolved conflicting advantages and limitations offered by generic or specific measures, by emphases on subjective or objective approaches, by brief or comprehensive assessments, or by combining or segregating status and preferences.

Many of the existing quality of life instruments have adopted scales and indices that had a prior existence as measures of health status. This has created a core of domains that are found in a majority of instruments: this core includes functioning in the activities of daily living, mobility, cognitive status, depression or morale, physical discomfort and self-perceived health. However, there are many other domains that appear in some instruments and not in all, so that the potential cumulative list is lengthy. There is little empirical work to identify which domains are most critical to a good quality of life.

Choosing between the numerous established instruments is a daunting task for the relatively inexperienced researcher or for the clinician wishing to enhance practice standards. An instrument which is widely used may appeal to researchers, reviewers and grant committees on the grounds of its substantial psychometric development, provision of norms, comparison with findings from previous pertinent studies, as well as the credence that comes from the consensus implicit in a large constituency of users.

Nevertheless, there are junctures in the growth of a field within the health sciences at which technological expediency can outstrip the slower work of fundamental understanding. At such points in the history of the maturation of a field the good can pre-empt the excellent. Whether this is the case for the current state of quality of life concept and measurement is a matter of judgment.

Non-computerized Assessment Procedures: Fundamental Assessment Issues

P. Logue

Duke University Medical Center, Durham, NC, USA

BASIC ASSESSMENT ISSUES

Just as individuals age, so do populations. The "graying of America" is a cliché that carries with it the inevitability of the normal aging process combining with the advancement of medical science. The average age of all industrialized countries is going up steadily. While, to some extent, these changes in basic demographics relate to improved infant mortality, there is also an increasing ability and willingness on the part of the medical profession to treat the ailments that may come with aging and extend the lifespan of individuals within the society. Control of ischemia risk factors, dialysis and organ transplant are all commonplace now but were much less advanced 30 years ago.

In many ways this demographic change is a very positive trend. Individuals at 50 now are no longer considered to be as old as they once were. There are many physically vigorous and cognitively intact individuals who function effectively well into their 70s, 80s and 90s. However, extension of life is not necessarily the extension of quality of life. With increasing age there is an increasing probability of dementing processes. Dementia is not the inevitable outcome of aging, but the diagnosis of dementing conditions increases significantly with each decade of life.

There are multiple potential dementing conditions. Some of these conditions are the by-products of physical disease and others of lifestyle choices made years earlier (*see* Table 27.1 for a partial listing of the more common dementing processes from the familiar DSM). The clear majority of dementing processes, however, fall into three general categories, Alzheimer's dementia, vascular disease-related dementia, and mixed dementias. While each has a progressive course, the potential for treatment and the speed and uniformity of the progression varies significantly. Precision of diagnosis is critical in the appropriate treatment and management in a geriatric dementia work-up.

Depression in the old, in combination with the normal aging process, can produce a condition that is treatable but that mimics the effects of central nervous system-based dementias. Depression in some cases may be the earlier preclinical precursor of dementia, but nevertheless, the accurate differential diagnosis of dementia and depression is of extraordinary importance. The consequences of a false-positive or false-negative diagnosis in dementia can be devastating. If a patient is labeled as having early-stage Alzheimer's syndrome, multiple negative consequences occur very quickly. Driving privileges, financial and medical decision-making and the independence that is critical to any person are all restricted and sometimes taken away. If the patient diagnosed with dementia is not demented but is depressed, unnecessary and potentially irreversible changes occur in the quality of the patient's life, even if the diagnosis is later changed. Similarly, if the patient does have a progressive dementia and proceeds to make decisions about finances, about health, or even about day-to-day instrumental activities of daily living, the consequences can be equally negative.

Table 27.1 DSM-IV: common dementing processes

Dementia of the Alzheimer's type
Vascular dementia
Dementia due to HIV disease
Dementia due to head trauma
Dementia due to Parkinson's disease
Dementia due to Huntington's disease
Dementia due to Pick's disease
Dementia due to Creutzfeldt–Jakob disease
Dementia due to other general medical conditions
Substance-induced persisting dementia
Dementia due to multiple etiologies
Dementia not otherwise specified

Diagnostic and Statistical Manual of Mental Disorders, 4th edn, p. 133.

In summary, the geriatric population is growing. As people age, they become more susceptible to potentially treatable conditions. These conditions can radically alter the quality of life and the ultimate prognosis and disposition for the successful management of the case.

ASSESSMENT PROCEDURES

The assessment of geriatric patients for dementing conditions demands considerable focus in assessment and knowledge of the scientific literature. These areas would include, at minimum, an understanding of the characteristics of the normal aging process and the salient behavioral/cognitive characteristics of the dementias. Necessary and desirable parameters of geriatric evaluations are as follows.

Necessary Characteristics of Any Assessment Procedure

Norms

Test results are significantly influenced by the age of the subject and premorbid functioning levels; therefore, any assessment

procedure utilized should have reasonably adequate norms that take age and educational level into consideration.

Validity and Reliability

Validity and reliability of the assessment procedure must be established and the relationship between the given dementing process and test scores well established within the scientific literature.

Depression and Cognition

Cognitive and affective diagnostic procedure should be utilized within the same battery, whether formally or informally, since the two interact so powerfully. The diagnosis of dementia vs. depression often resolves itself down to the proportion of each.

Depth/Breadth of Assessment

Sufficient breadth and depth of assessment is required so that patients can be followed over time, in improving and deteriorating conditions, so that unsuspected conditions are not easily missed in a routine assessment.

Desirable Characteristics

Short

Relative brevity, even in a multi-factorial assessment, is highly desirable. Geriatric patients become impatient, threatened and exhausted when test batteries become too lengthy. The procedure at the end of the assessment process may be less valid than that at the beginning of the assessment process.

Practical

Ideally, along with reliability and validity, the assessment encompasses those variables that are clinically important. While reaction time may be highly sensitive at the bedside, in day-to-day clinical practice memory assessment or assessment of attention is much more likely to be broadly useful. The geriatric patient is more likely to be uncooperative and sometimes appropriately contemptuous of "kid" games. If a patient can perceive the relevance of the procedure, whether or not he/she feels threatened by it, the test results are more likely to be valid and reliable.

Numbers

Quantification of the test result is very desirable, since multiple successive assessments may be done that trace the course of the syndrome or the effects of medication.

Models

It is highly desirable that the tests, in aggregate, fit together into a relatively coherent model of cognitive assessment and include formal and informal assessment of at least the following:

- General abilities.
- Speech and language.
- Constructional abilities.
- Motor functions.
- Memory and learning.
- Attention and concentration.
- Judgment and problem-solving abilities.
- Speed of processing.

At times, these assessments may be as informal as just listening to the patient, but are necessary descriptive parameters of the assessment.

NON-COMPUTERIZED ASSESSMENT OF COGNITIVE FUNCTION

Selection of Assessment Tools

As in all patient populations, neuropsychological assessment of older individuals begins with a thorough understanding of the referral question and a clear goal as to the purposes of the evaluation. The specific functional areas of cognition to be tested, and therefore the format and comprehensiveness of the entire evaluation, should be based on the initial referral question and targeted at achieving the specific goals of the referring healthcare provider. Nowhere is it more important to tailor the assessment battery to the specific diagnostic concerns, while considering the unique abilities and limitations of the patient population, than with a geriatric population. Test selection must optimally allow for an in-depth evaluation of the cognitive areas of concern, while keeping battery length and difficulty level manageable for the aging patient. Ultimately, the battery "should discriminate maximally between normal aging and CNS disorders such as the different dementias"[1]. As these authors state further, a successful test battery should also allow differentiation among the various common subtypes of dementia, as well as between dementia and affective disturbance.

Screening Evaluations vs. Full Batteries

Even when the referral question implies a broad assessment of overall cognitive abilities for the purpose of identifying the presence or absence of neuropsychological deficits, the use of a brief but well-rounded neuropsychological screening measure can be prudent. Such tools typically allow the examiner to quantify gross deficits against normative data in order to classify the tested individual as "normal" or "abnormal" in particular cognitive areas of functioning. Cut-off scores and the number of abnormal scores necessary for rating an individual's performance on such measures against target normative populations usually allow for qualitative classifications ranging from superior to severely impaired. Depending upon the psychometric soundness of the screening instrument, the examiner may be able to draw conclusions with respect to specific cognitive abilities, or may be limited to a judgment of impaired or not impaired.

The benefits of using a brief screening measure for cognitive evaluation are obvious; they tend to require less administration time for both the patient and the examiner, and they are typically less labor-intensive and intimidating for the patient. Most commercially available cognitive screens are easily scored and provide feedback for recommendations quickly, which is an asset in inpatient settings or other situations when the patient's treatment plan and disposition considerations may be urgent. As with most things in life, however, time-saving procedures may sacrifice quality. Even the most widely accepted brief cognitive screens lack the diagnostic sensitivity and specificity of the more comprehensive neuropsychological battery, particularly when

they generate only a single score or are limited to largely verbal measures. When choosing to use a cognitive screen for neuropsychological evaluation of a geriatric patient, it is important to balance our desire to spare the patient a lengthy assessment time with a genuine quest to garner the most reliable diagnostic data available. This goal may best be achieved by augmenting a brief cognitive screen, with individual neuropsychological measures aimed at the more detailed evaluation of specific cognitive abilities or affective characteristics.

One neuropsychological screening assessment that has achieved wide acceptance with use in a geriatric population is the Dementia Rating Scale (DRS)[2]. This scale yields scores for attention, initiation/perseveration, construction, conceptualization and memory, and compares individuals' performances to a normative base of subjects with known Alzheimer's disease. In providing such a comparison population, the instrument controls for normal aging variation. In this way, the measure offers easily referenced cut-off scores for quick classification of outcomes as being consistent with dementia or not.

A more recent tool available to clinicians is the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS)[3]. While supportive literature for its use in diagnosing dementia in the geriatric population is only now being gathered, the RBANS has the advantage of being available in parallel forms, thus allowing serial assessment. Repeatability is a valuable feature for a cognitive screen to have, especially in documenting recovery of function after a reversible neurological injury and in demonstrating progressive decline in the degenerative dementias. The authors refer readers to published review articles and commercial catalogs for the clinical findings and availability of these and other neuropsychological screening measures.

In many cases, the discrimination between dementia and pseudodementia, or the differential diagnosis between types of dementing illnesses, cannot be achieved through use of a brief cognitive screen. In these cases, a more comprehensive test battery may be the only method by which to quantify and qualify specific areas of deficits into a pattern consistent with a diagnostic picture. In selecting tests for such a battery, one may focus on specific symptomatic cognitive areas or may seek to assess global cognitive functioning with a combination of neuropsychological measures. There are numerous individual neuropsychological tests developed to assess specific cognitive functional areas (Table 27.2). The combination of these tests into a clinical battery may be based on theoretical concepts or assessment approaches; some clinicians prescribe to use of standard batteries, such as the Halstead–Reitan and the Luria–Nebraska, while others combine individual neuropsychological measures into a more flexible or "process approach" battery. Whatever one's theoretical basis, consistency and rigor in assessment procedures remains the most effective way for a clinician to develop his/her own personal bank of base rates and characteristic result profiles.

Table 27.2 Examples of neuropsychological tests for specific cognitive functions

Cognitive functional area	Example neuropsychological tests
Intellectual functioning	WAIS-R or WAIS-III
	Ravens Progressive Matrices (non-verbal)
	Peabody Picture Vocabulary Test (verbal)
	Mini-Mental State Examination (MMSE)
Attention/concentration functioning	Verbal Series Attention Test
	Continuous Performance (2 and 7) Test
	Stroop Test
	Digit Span
	PASAT
Executive functioning	Wisconsin Card Sorting Test
	Short Category Test
	Trail Making Test
	Verbal Fluency/Figural Fluency
Memory and learning functioning	WMS-R or WMS-III (logical memory and visual reproduction)
	CVLT, RAVLT-R, HLVT-R
	Selective Reminding (Buschke or Levin)
	Warrington Facial Recognition Memory
	Benton Visual Retention Test
Language functioning	Western Aphasia Battery
	Wepman Aphasia Screening
	Multilingual Aphasia Examination
	Boston Naming Test
	Controlled Verbal Fluency
	Animal Fluency
Visuospatial/visuomotor functioning	Benton Facial Recognition
Judgment of line orientation	Rey-O Complex Figure
	Trail Making Test
Motor functioning	Finger Tapping
	Grooved Pegboard
	Grip Strength
	Boston Apraxia Examination
Emotional/personality functioning	Geriatric Depression Scale
	Beck Depression Inventory
	Multiscore Depression Inventory
	MMPI-2

Specific Cognitive Functional Areas

Intellectual functioning is one of the broader functional areas assessed and may include assessment of fluid and crystallized knowledge. It is not a unitary entity but instead consists of multiple functions, including the ability to acquire, process, categorize and integrate information. Intellectual functioning intimately involves use of memory and learning, visuospatial skills, attentional abilities, expressive and receptive language, and aspects of adaptive reasoning and organizational structure. Assessment may involve evaluation of verbal intellect, non-verbal (performance) intellect, or overall intellectual abilities.

Attention and concentration abilities are critical for neuropsychological functioning. More complex processing depends on these primary functions. Their scope involves speed of information processing, accuracy of discrimination, selectivity and use of a heightened state of awareness. Successful evaluation of attention/concentration skills is necessary for proper interpretation of other neuropsychological findings, including memory and learning.

Executive functioning is a complex phenomenon, which answers the question of how or whether one will do something. It involves the capacity to initiate activity and the process of self-monitoring and interpreting feedback. Executive functions include the planning and sequencing strategies that facilitate goal-directed behaviors. Assessment of executive functioning should include testing at varying levels of complexity to obtain an adequate picture of the patient's mental flexibility.

Memory and learning assessment is at the core of most neuropsychological evaluations of the elderly. A complete evaluation should examine verbal memory (contextual and non-contextual) and visual memory (independent of constructional ability), and should address acquisition, retention and recognition through somewhat independent means. The distinction between deficits in encoding and deficits in retrieval of newly-learned information can be crucial in differential diagnosis of the various dementias.

Expressive and receptive language abilities should be assessed directly, including auditory and reading comprehension, repetition skills and the ability to follow simple commands (praxis). Specific language characteristics, including visual confrontation

naming and word fluency, may be evaluated with multiple or overlapping measures to increase the reliability of findings. Whenever possible it may be helpful to assess language abilities in both the oral and written modalities to determine the generalizability of language deficits.

Visuospatial functioning assessment should include the evaluation of near visual acuity, processing of visual stimuli, recognition of shapes, colors and forms, and overall spatial orientation of objects in space and during motor tasks. The copying and drawing of geometric or figural designs can directly assess visual perception.

Assessment of motor functioning should include both gross and fine motor abilities. Manual dexterity and gross manual strength are both important and may yield clues to hemispheric differences. Motor planning can best be evaluated through completion of complex, repetitive motor movements and with traditional go–no go motor tasks.

Emotional/personality functioning is one of the most important areas to be assessed in the elderly population. Affective disturbance can contribute to multiple cognitive deficits; therefore, the differentiation between emotional dysfunction and true CNS abnormality is essential in creating an accurate diagnostic profile. Generational differences must be considered when assessing elderly patients for signs and symptoms of depression and anxiety, and stereotypical views of expected emotional functioning of older individuals must be avoided.

ADDITIONAL RESOURCES

What has been offered in this chapter represents a brief introduction and overview of the basic concepts of non-computerized neuropsychological assessment in geriatric patients. The field of geriatric neuropsychology, while still relatively new in comparison with other disciplines, is growing exponentially as the world population continues to include more people at older ages. There exist a good number of valuable references and resources for both professionals working with older individuals, and for caregivers who must consider whether referral of their loved one for neuropsychological evaluation is indicated. The authors encourage healthcare professionals and caregivers alike to access their local centers on aging, the national Alzheimer's Association, and the various clinical neuropsychological associations (e.g. National Academy of Neuropsychology) to obtain further information on cognitive assessment and intervention in older individuals. An extensive list of reading references is also being included to encourage further exploration of related topics.

Mini-Mental State Examination

Joseph R. Cockrell and Marshal F. Folstein*

Department of Psychiatry, Medical University of South Carolina, Charleston, SC, USA, and
**New England Medical Center, Boston, MA, USA*

The Mini-Mental State Examination (MMSE) is a 10-minute bedside measure of impaired thinking in undeveloped, uneducated, diseased, or very old populations. The summed score of the individual items indicates the current severity of cognitive impairment. Deterioration in cognition is indicated by decreasing scores of repeated tests. Scores are reliable between tests and between raters[1] and correlate with other mental tests, electroencephalography[2], computerized tomography[3], magnetic resonance imaging[4], single photon emission computed tomography (SPECT) scan[5], CSF proteins and enzymes[6,7] and brain biopsy synapse numbers[8].

To administer the MMSE, gain the patient's cooperation by asking him if there is a memory problem and then asking permission to test his memory. During testing, praise successes and ignore failures so as to avoid emotional reactions that will compromise cooperation and performance.

The items of the MMSE include tests of orientation, registration, recall, calculation and attention, naming, repetition, comprehension, reading, writing and drawing. Level of consciousness is rated on a scale from coma to fully alert, but the consciousness rating is not summed with the other items. If all items are answered correctly, the score is 30. The mean score for a community-dwelling population over 65 years of age is 27, with a standard deviation of 1.7[1]. The score is lower in those who completed comparatively fewer years of education and who have diagnosable diseases[9–11]. Patients with dementia, delirium, mental retardation, Parkinson's disease, stroke and some cases of depression score lower than normal controls[1,12]. Alzheimer's disease patients lose 3–4 points per year of illness after the onset of memory disturbance, although there is wide variability in this phenomenon[13,14].

naming and word fluency, may be evaluated with multiple or overlapping measures to increase the reliability of findings. Whenever possible it may be helpful to assess language abilities in both the oral and written modalities to determine the generalizability of language deficits.

Visuospatial functioning assessment should include the evaluation of near visual acuity, processing of visual stimuli, recognition of shapes, colors and forms, and overall spatial orientation of objects in space and during motor tasks. The copying and drawing of geometric or figural designs can directly assess visual perception.

Assessment of motor functioning should include both gross and fine motor abilities. Manual dexterity and gross manual strength are both important and may yield clues to hemispheric differences. Motor planning can best be evaluated through completion of complex, repetitive motor movements and with traditional go–no go motor tasks.

Emotional/personality functioning is one of the most important areas to be assessed in the elderly population. Affective disturbance can contribute to multiple cognitive deficits; therefore, the differentiation between emotional dysfunction and true CNS abnormality is essential in creating an accurate diagnostic profile. Generational differences must be considered when assessing elderly patients for signs and symptoms of depression and anxiety, and stereotypical views of expected emotional functioning of older individuals must be avoided.

ADDITIONAL RESOURCES

What has been offered in this chapter represents a brief introduction and overview of the basic concepts of non-computerized neuropsychological assessment in geriatric patients. The field of geriatric neuropsychology, while still relatively new in comparison with other disciplines, is growing exponentially as the world population continues to include more people at older ages. There exist a good number of valuable references and resources for both professionals working with older individuals, and for caregivers who must consider whether referral of their loved one for neuropsychological evaluation is indicated. The authors encourage healthcare professionals and caregivers alike to access their local centers on aging, the national Alzheimer's Association, and the various clinical neuropsychological associations (e.g. National Academy of Neuropsychology) to obtain further information on cognitive assessment and intervention in older individuals. An extensive list of reading references is also being included to encourage further exploration of related topics.

Mini-Mental State Examination

Joseph R. Cockrell and Marshal F. Folstein*

Department of Psychiatry, Medical University of South Carolina, Charleston, SC, USA, and
**New England Medical Center, Boston, MA, USA*

The Mini-Mental State Examination (MMSE) is a 10-minute bedside measure of impaired thinking in undeveloped, uneducated, diseased, or very old populations. The summed score of the individual items indicates the current severity of cognitive impairment. Deterioration in cognition is indicated by decreasing scores of repeated tests. Scores are reliable between tests and between raters[1] and correlate with other mental tests, electroencephalography[2], computerized tomography[3], magnetic resonance imaging[4], single photon emission computed tomography (SPECT) scan[5], CSF proteins and enzymes[6,7] and brain biopsy synapse numbers[8].

To administer the MMSE, gain the patient's cooperation by asking him if there is a memory problem and then asking permission to test his memory. During testing, praise successes and ignore failures so as to avoid emotional reactions that will compromise cooperation and performance.

The items of the MMSE include tests of orientation, registration, recall, calculation and attention, naming, repetition, comprehension, reading, writing and drawing. Level of consciousness is rated on a scale from coma to fully alert, but the consciousness rating is not summed with the other items. If all items are answered correctly, the score is 30. The mean score for a community-dwelling population over 65 years of age is 27, with a standard deviation of 1.7[1]. The score is lower in those who completed comparatively fewer years of education and who have diagnosable diseases[9–11]. Patients with dementia, delirium, mental retardation, Parkinson's disease, stroke and some cases of depression score lower than normal controls[1,12]. Alzheimer's disease patients lose 3–4 points per year of illness after the onset of memory disturbance, although there is wide variability in this phenomenon[13,14].

Misinterpretations of scores result from several misconceptions about the test. The MMSE is not a complete mental status examination or a complete neuropsychological examination. The MMSE does not define a clinical or pathological diagnostic category, such as dementia or brain tumor or organicity. The score does not measure decline from a previous level unless tests are repeated over time. The score does not tell the whole story. Individual items are useful for understanding the situation of the patient, since they indicate whether the patient can follow instructions, read and write. Finally, the MMSE is a weak measure of competence or disability. Competence, handicap and disability must be assessed by procedures designed for that purpose.

IQCODE: Informant Interviews

A. F. Jorm

Centre for Mental Health Research, The Australian National University, Canberra, Australia

In assessing patients for dementia, informants are a valuable source of information, complementing other sources such as cognitive testing. The strengths of informant data include:

- *Everyday relevance*. Informants can report on how the patient is functioning in everyday cognitive tasks. Cognitive tests, by contrast, generally involve artificial tasks removed from daily life.
- *Acceptability to patients*. Formal cognitive testing can be distressing to some people because of the limitations it reveals. However, informant interviews do not directly confront the patient's limitations.
- *Longitudinal perspective*. It is often useful to know how a patient is functioning compared to earlier in life. An interview with an informant who has known the patient for many years can provide this.
- *Ease of administration*. If necessary, informant data can be collected by telephone or mail. In some research situations, it has even been used to assess deceased subjects.
- *Cross-cultural portability*. Informant data may have greater validity than cognitive testing for patients who are from culturally different backgrounds[1].

While informant interviews are widely used in clinical practice, there is now a range of standardized informant interviews and questionnaires available for quantifying this information. Probably the most widely used and researched is the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE)[2]. The IQCODE is a 26-item questionnaire that asks the informant about cognitive changes over the previous 10 years. Items cover memory and intellectual functioning and are rated on a five-point scale from "1. Much improved" to "5. Much worse". Originally, the IQCODE was designed as an interview but it is more commonly used as a self-administered questionnaire. There is now a short 16-item IQCODE which performs as well as the original. Translations of the IQCODE are available in a range of languages. The various versions are available on the Web at http://www.anu.edu.au/iqcode/.

Principal component analysis of the IQCODE items have shown that it measures a general factor of cognitive decline. Validity studies have found that the IQCODE correlates moderately with cognitive screening tests such as the Mini-Mental State Examination (MMSE) (mean $r = 0.59$ over seven samples). Correlations with indicators of premorbid ability, such as the National Adult Reading Test (NART) and years of education are repeatedly found to be near zero.

A meta-analysis of seven studies directly comparing the IQCODE with the MMSE as a screening test for dementia found that the IQCODE performed at least as well as the

IQCODE: Informant Interviews

A. F. Jorm
Centre for Mental Health Research, The Australian National University, Canberra, Australia

In assessing patients for dementia, informants are a valuable source of information, complementing other sources such as cognitive testing. The strengths of informant data include:

- *Everyday relevance*. Informants can report on how the patient is functioning in everyday cognitive tasks. Cognitive tests, by contrast, generally involve artificial tasks removed from daily life.
- *Acceptability to patients*. Formal cognitive testing can be distressing to some people because of the limitations it reveals. However, informant interviews do not directly confront the patient's limitations.
- *Longitudinal perspective*. It is often useful to know how a patient is functioning compared to earlier in life. An interview with an informant who has known the patient for many years can provide this.
- *Ease of administration*. If necessary, informant data can be collected by telephone or mail. In some research situations, it has even been used to assess deceased subjects.
- *Cross-cultural portability*. Informant data may have greater validity than cognitive testing for patients who are from culturally different backgrounds[1].

While informant interviews are widely used in clinical practice, there is now a range of standardized informant interviews and questionnaires available for quantifying this information. Probably the most widely used and researched is the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE)[2]. The IQCODE is a 26-item questionnaire that asks the informant about cognitive changes over the previous 10 years. Items cover memory and intellectual functioning and are rated on a five-point scale from "1. Much improved" to "5. Much worse". Originally, the IQCODE was designed as an interview but it is more commonly used as a self-administered questionnaire. There is now a short 16-item IQCODE which performs as well as the original. Translations of the IQCODE are available in a range of languages. The various versions are available on the Web at http://www.anu.edu.au/iqcode/.

Principal component analysis of the IQCODE items have shown that it measures a general factor of cognitive decline. Validity studies have found that the IQCODE correlates moderately with cognitive screening tests such as the Mini-Mental State Examination (MMSE) (mean $r = 0.59$ over seven samples). Correlations with indicators of premorbid ability, such as the National Adult Reading Test (NART) and years of education are repeatedly found to be near zero.

A meta-analysis of seven studies directly comparing the IQCODE with the MMSE as a screening test for dementia found that the IQCODE performed at least as well as the

MMSE[3]. However, in clinical practice informant questionnaires and cognitive screening tests are complementary rather than competitors. A simple graphical way of combining the IQCODE and the MMSE for screening purposes is provided by the Demegraph[4]. This can be downloaded from the Web at http://www.mhri.edu.au/biostats/demegraph/.

One weakness of the IQCODE and other informant scales is that they can be biased by the affective state of the informant and the quality of the relationship between the informant and the patient. Cognitive decline is perceived to be greater where the informant is anxious or depressed or where there is a poor relationship.

Staging Dementia

Barry Reisberg, Gaurav Gandotra, Arshad Zaidi and Steven H Ferris

Aging and Dementia Research Center, New York University School of Medicine, USA

Dementia is a progressive pathologic process extending over a period of many years. Clinicians and scientists have long endeavored to describe the nature of this progression. Such descriptions have generally been encompassed within two broad categories, viz. global staging and more specific staging, sometimes referred to as axial or multi-axial staging. A comparison of the major current dementia staging systems with the most widespread mental status assessments in Alzheimer's disease, the major cause of dementia, is shown in Table 1, which illustrates some of the major potential advantages of staging. These advantages include: (a) staging can identify premorbid but potentially manifest conditions that may be associated with dementia, such as age-associated memory impairment, a condition which is not differentiated with mental status or psychometric tests; (b) staging can be very useful in identifying subtle, identifiable, predementia states, such as mild cognitive impairment (MCI), wherein mental status assessments and psychometric tests, while frequently altered, are generally within the normal range and consequently are not reliable markers; and (c) staging can track the latter 50% of the potential time course of dementias such as AD, when mental status assessments are virtually invariably at bottom (zero) scores. Furthermore, apart from its utility in portions of dementia where mental status and psychometric assessments are out of range or clearly insensitive, there is evidence that staging procedures can more accurately and sensitively identify the course of dementia in the portion of the condition that is conventionally charted with mental status assessments. This latter evidence comes from longitudinal investigation of the course of AD[1], pharmacologic treatment investigation of AD[2] and study of independent psychometric assessments of AD[3]. Another seeming advantage of staging procedures in comparison with mental status or psychometric assessment of AD and other dementias is in identifying the management concomitants of severity assessments[4]. Staging procedures have also been successfully applied post mortem to assess retrospectively the diagnoses of a diverse assortment of dementia-related cases available for "brain banking" but on which no ante mortem clinical data were available[5]. Similarly,

post mortem retrospective staging procedures have been successful in establishing remarkably robust clinicopathologic correlations in longitudinally-studied AD cohorts[6,7].

GLOBAL STAGING

Efforts to stage progressive dementia globally can be traced back at least to the early nineteenth century, when the English psychiatrist, James Prichard, described four stages in the progression of dementia: "(1) impairment of recent memory, (2) loss of reason, (3) incomprehension, (4) loss of instinctive action"[8]. More recently, the American Psychiatric Association's 1980 *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edn (DSM-III)[9] recognized three broad stages in its definition of primary degenerative dementia. Subsequently, in 1982, two more detailed global descriptions of the progression of dementia were published. One of these, the Clinical Dementia Rating (CDR) scale[10] described five broad stages from normality to severe dementia. The other, the Global Deterioration Scale (GDS)[11], identified seven clinically recognizable stages, from normality to most severe dementia of the Alzheimer type. These two global staging instruments, the GDS and the CDR, are generally compatible except that the GDS is more detailed and specific and identifies two stages that the original CDR staging does not. One of these is a stage in which subjective complaints of cognitive deficit occur (GDS stage 2). These subjective complaints are now recognized as occurring very commonly in aged persons[12–14] and consensus workgroups have called attention to the importance of these symptoms and the need for more detailed study of their nature and treatment[15–17]. Although this stage of subjective complaints continues to be identified only by the GDS staging system, recent studies have indicated that persons with these complaints are at increased risk for subsequent overt dementia[18,19]. Also, at the other end of the pathologic spectrum, the CDR did not identify any stage beyond that in which dementia patients "require much help with personal care" and are "often incontinent", whereas the GDS identifies a final seventh GDS stage in which patients are already incontinent and over the course of which language and motor capacities are progressively lost. Subsequently, two further stages were suggested for the CDR, corresponding to the GDS stage 7 range[20–22].

Staging procedures have been shown to be valid and reliable methods for assessing the magnitude of pathology in AD and related dementing conditions. This validity and reliability is illustrated in this brief review for the GDS, probably the most detailed and explicit staging procedure.

The validity of the GDS has been demonstrated in several ways. Cross-sectional studies have confirmed the consistency of the ordinal sequence and the optimal weighting of the hierarchically sequenced items embodied in the GDS stages in aging and progressive Alzheimer's disease (AD)[22–24]. Thus, the specific impairments characteristic of each stage almost always follow the impairments described for the previous stage. Also, the grouping of impairment characteristics within stages appears to be optimal.

For example, naturalistic study has supported the identification of staging phenomena, largely identical to the GDS stages, by independent lay-person observers. In this study[23], a 30-item questionnaire derived from the GDS was completed by a relative or caregiver for each of 115 patients with varying degrees of dementia. Principal components analysis was used to combine the items into a single composite scale which more reliably represents distances between the 30 clinical manifestations along the continuum of cognitive decline. The study found that "the scale scores for the clinical manifestations were observed to cluster into relatively discrete groups, suggesting naturally occurring stages or phases. Objective cluster analysis methods further confirmed the presence of distinct transitions along the cognitive decline continuum". It concluded that the "utility of empirically derived scale values in staging the course of primary degenerative dementia is suggested".

The relationship between the GDS stages and mental status assessments, other dementia assessments, scores on cognitive tests and other objective tests and *in vivo* assessments of brain change in aging and progressive dementia have been studied in considerable detail[11,24]. These studies have indicated significant correlations between all of these measures of dementia severity and the GDS stages. However, the strongest relationships have been observed between comprehensive dementia assessments, such as the Mini-Mental State Examination (MMSE)[25], and the progression of dementia on the GDS[24]. The GDS also correlates well with evaluations of actual functioning and activities of daily living in AD[26] and with independent physical markers of AD progression, such as changes in neurologic reflexes[27]. Thus, the construct validity of the GDS has been well substantiated.

At least six separate studies have examined the reliability of the GDS[28–33]. Reliability coefficients have ranged from 0.82 to 0.97 in these studies, using disparate procedures in diverse settings. These studies have indicated that the GDS is at least as reliable as any other instrument upon which clinicians rely, such as the MMSE. In a reliability study in a nursing home setting[32], the GDS was found to be somewhat more reliable than the MMSE. Importantly, GDS staging has also been shown to be a reliable procedure when assessed using a telephone format[33].

Global staging scales such as the GDS have certain important advantages in dementia assessment. First and foremost, these scales are strongly anchored to the clinical symptoms, behaviour and functional changes in progressive degenerative dementia and particularly that of Alzheimer's disease. Consequently, they discourage misdiagnosis. Unlike many mental status and other dementia test instruments, global stages are relatively stable over time and relatively resistant to practice effects. Equally importantly, global staging instruments are minimally influenced by educational background and socioeconomic status, whereas mental status and similar assessments are strongly influenced by such factors. Also, global staging, and in particular the GDS, covers the entire range of pathology in central nervous system (CNS) aging and progressive dementia, whereas, for example, mental status assessments and most psychometric tests entirely fail to distinguish GDS stages 1 and 2. Occasionally, patients may display GDS stage 3 symptomatology and still score a perfect 30 on the MMSE. Uncommonly, dementia patients may display GDS stage 4 symptomatology, and still score a perfect 30 on the MMSE. Much more commonly, patients may display the clear-cut dementia symptomatology characteristic of GDS stage 4 and achieve MMSE scores which are near-perfect or within the so-called "normal" range. At the other end of the pathologic spectrum, most patients at GDS stage 6 achieve only bottom scores on traditional psychometric tests. Over the entire course of the GDS 7 stage, nearly all patients attain only zero scores on the MMSE. The GDS, however, describes a final seventh stage, over the course of which patients may survive for many years.

AXIAL AND MULTI-AXIAL STAGING

The observation that the progression of dementia pathology is accompanied by progressive changes in more specifically defined processes has resulted in efforts to stage dementia in terms of those processes. Generally, axial staging has attempted to exploit progressive changes in cognition or functioning, although attempts have also been made to stage hierarchically progressive mood and behavioural changes, progressive motoric changes and

progressive neurologic changes, as well as other observable concomitants of dementia. These efforts can be traced back more than 30 years to the work of de Ajuriaguerra and associates[34–36], Swiss investigators who were strongly influenced by Piaget's investigations of the stages of normal infant and childhood development. More recently, Cole and co-workers in Canada employed this approach in their Hierarchic Dementia Scale[37–39]. A similar approach was pursued, apparently independently, by Haycox[40] in the USA and Gottfries *et al.*[41] in Sweden.

The CDR staging has a "sum of boxes" approach that employs a hierarchical, multi-axial-like procedure[21]. Based upon their seven-stage GDS, Reisberg and associates also described axial and multi-axial concomitants of progressive dementia[42,43]. Ultimately, these latter descriptions resulted in the most detailed hierarchic staging of progressive dementia proposed to date, a 16-stage measure of progressive functional change. This latter assessment, termed Functional Assessment Staging or FAST[44], has been enumerated to be optimally concordant in dementia of the Alzheimer type, with the corresponding GDS stages, discussed above. The developers of the FAST note several advantages of this measure, including: (a) the FAST is capable of describing the entire course of dementia of the Alzheimer type, ordinally (i.e. hierarchically), in unprecedented detail; (b) the scale can assist in differentiating dementia of the Alzheimer type from other dementia processes[22,45,46]; (c) the scale can assist in identifying premature and potentially remediable functional changes in AD patients (e.g. premature loss of ambulation due, for example, to the side effects of medication)[22,45,46]; (d) the scale permits the retrospective as well as prospective examination of the temporal course of AD[6,7]; and (e) the scale is the only current measure that permits the detailed staging of severe AD[3,26,47]. A strong relationship between this FAST procedure and comprehensive cognitive assessments such as the MMSE has long been noted[48,49]. However, because the MMSE and other cognitive modalities bottom out prior to the final five to eight FAST substages, complete concurrent validation and examination of the FAST had to await the development of cognitive measures useful in most severe dementia. Such measures were developed towards the end of the twentieth century and do, in fact, evidence strong relationships with the final FAST stages[3]. Subsequent work showed equally strong relationships between this latter portion of the FAST and ostensibly cognition-independent neurologic reflex changes[27] as well as hippocampal neuropathologic changes in volume[6], cell number[7], and neurofibrillary changes[7] with the advance of AD as per the FAST stages and substages. The correlation between the advance of AD as measured with the FAST in the latter portion of the course of AD, generally after the MMSE bottom (zero) point, and cognitive, neurologic reflex and neuropathologic hippocampal measures are generally approximately 0.8–0.9, comparable to the correlation between the FAST and the MMSE in the MMSE sensitive portion of the FAST staging assessment. Because of these properties and others, the FAST, as well as the GDS staging more generally, has proved of widespread utility. For example, in the USA, the FAST staging procedure is currently utilized as the Medicare mandated "gold standard" for hospice admission (Health Care Finance Administration, 1998) and the FAST and GDS have been utilized to survey the severity mix in the US National Institute on Aging Special Care Units consortium[50]. Importantly, because of the sensitivity of the FAST staging procedure to the course of AD, not only over the final seventh stage when the MMSE is zero, but also over the course of FAST stage 6, when patients still score on measures such as the MMSE, the FAST measure has shown a significant neuroprotective effect on course in a multicenter drug trial, whereas the MMSE was not sensitive to change in this study[2].

SUMMARY

Staging can be useful in identifying potential treatments for AD and other dementias, as well as in assessing the course and the management needs of the dementia patient, and also in the diagnosis and differential diagnosis of dementing disorders. In providing an overview of the course of dementias such as AD, from the initial to final clinical symptoms, staging is uniquely useful. Staging is also uniquely useful in assessment at various specific points in the evolution of dementing processes. Very importantly, staging can uniquely relate to management needs and the general management import of dementing processes.

ACKNOWLEDGEMENTS

This work was supported in part by US DHHS Grants AG03051 and AG08051 from the National Institute on Aging of the US National Institutes of Health, by Grant 90 AR2160 from the US Department of Health and Human Services Administration on Aging, and by the Zachary and Elizabeth M. Fisher Alzheimer's Disease Education and Resources Program of the New York University School of Medicine.

Psychogeriatric Assessment Scales

A. F. Jorm

Centre for Mental Health Research, The Australian National University, Canberra, Australia

The Psychogeriatric Assessment Scales (PAS) aim to assess the clinical changes of dementia and depression using a set of continuous scales[1]. The PAS consists of two parts, an interview with the patient and an interview with an informant who knows the patient well. The purpose of interviewing both the patient and an informant is to acquire different perspectives on the patient's impairments. The PAS consists of six scales, three derived from the interview with the patient and three from the interview with the informant. The content of these scales is as follows:

Patient Interview:

- *Cognitive impairment*. This consists of brief tests of cognitive functioning and is sensitive to dementia. It correlates highly with the Mini-Mental State Examination.
- *Depression*. This asks about common symptoms of depression. It correlates highly with the Goldberg Anxiety and Depression Scales.
- *Stroke*. This scale asks about symptoms of cerebrovascular disease and is useful in differentiating Alzheimer's dementia from vascular dementia. It correlates highly with the Hachinski Ischemic Score.

Informant Interview:

- *Cognitive decline*. This scale asks questions about everyday cognitive functioning and is sensitive to dementia. It correlates highly with the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE).
- *Behaviour change*. The questions in this scale cover aspects of behaviour that could cause interpersonal difficulties and are sensitive to both depression and dementia.
- *Stroke*. The scale involves the same questions as asked of the patient, but provides an independent source of information.

Each scale yields a score along a continuum, and norms are available to show how rare a given score is in the population. The scores can be plotted as a graph to give a readily interpretable summary of the patient's pattern of impairments.

The PAS scales were derived from a principal component and latent trait analysis of items that were designed to cover the ICD-10 and DSM-III-R diagnostic criteria for dementia and depression[1]. Items for the PAS scales were selected to have steep slopes (i.e. to be highly discriminating items) and to have a range of thresholds (i.e. to cover a range of severity).

Validity has been assessed against clinical diagnoses of dementia and depression using receiver operating characteristic (ROC) analysis[1,2]. The Cognitive Impairment and Cognitive Decline scales perform well as screening tests for dementia, while the Depression scale performs well as a screening test for depression. The Behaviour Change scale is non-specific, being affected by both dementia and depression. The Stroke scales perform well at discriminating vascular from non-vascular (mainly Alzheimer's) types of dementia.

The PAS materials and User's Guide[3] can be downloaded free from the Web at http://www.mhri.edu.au/pas/. For people who do not have Internet access, printed copies are available by writing to: PAS Project, Centre for Mental Health Research, Australian National University, Canberra 0200, Australia. The PAS is available in a number of other languages, including French, German, Italian, Chinese and Korean. For details on their availability, write to the above address.

Computer Methods of Assessment of Cognitive Function

T. W. Robbins and Barbara J. Sahakian

Departments of Experimental Psychology and Psychiatry, University of Cambridge, UK

Almost 20 years ago, the Royal College of Physicians recommended the use of automated testing procedures in assessing the deficits of patients with dementia, particularly in the context of clinical trials, because of their greater reliability and objectivity[1]. Since then, there have been several developments that have capitalized on the explosion of computer technology and its general availability over the past decade, which have been the subject of earlier reviews[2–5].

The advantages and disadvantages of computerized testing can readily be summarized. Apart from the obvious objectivity and accuracy of the measures and the standardization of the administration of the tests themselves, there are potential gains in patient compliance. Paper and pencil tests and clinical assessment interviews are generally admitted not to be popular with patients, perhaps because of their confrontational and formal nature. In our experience, computerized tests are also preferred by clinical assessors, who find that they have more time to focus on the patient during testing, rather than upon the presentation of the test material and data recording. Well-designed computerized tests that provide adequate feedback may provide some incentive for patients to do well, thereby avoiding the difficult problems of interpretation provided by lack of motivation. On the other hand, there is often little to be gained from the mere administration of standard tests in a computerized format, except in terms of the logging and storage of the data. Certainly it is infeasible to dispense with the human assessor during computerized testing; indeed, it is vital that a trained individual is present during such testing. And requesting patients to interact with certain novel and complex forms of interface, such as keyboards and other complex manipulanda, may serve only to confuse assessment by providing the patients with an extra set of problems to master. In recent developments, these problems have been circumvented, at least in part, by the use of touch-sensitive screens, which require the patient only to respond directly to the test stimuli themselves without imposing further demands by requiring them to divide their attention between a screen and a keyboard. It can also be argued that computerized assessment removes some of the creative flexibility that an experienced clinical neuropsychologist can bring to patient testing; however, this, too, can largely be avoided by the use of sufficiently flexible computerized contingencies.

In this brief review, we will concentrate on some prominent batteries that have been used for assessing cognitive functioning in the elderly. These batteries share some common principles, but also emphasize different aspects of design and administration.

EARLY ATTEMPTS: A COMPUTERIZED EVERYDAY MEMORY BATTERY

Crook and his colleagues took into account clinical, theoretical and psychometric considerations in designing their battery which, however, no longer appears to be generally available. However, their design historically represented a methodological advance in several respects and so we describe its main features below. In particular, they addressed the problem of ecological validity by simulating everyday memory situations, such as memory for faces, the locations of objects, telephone numbers and shopping lists, narrative memory for a simulated news broadcast and topographical memory for routes[6–8]. This required at that time quite advanced computer technology, including the use of the touch-sensitive screen, laser disk and video recordings. Thus, for example, one test involves viewing a live colour video recording of people introducing themselves. The subject has to learn the names that go with the faces and retain them over a 40 min delay. Tests of immediate memory for telephone numbers are administered with the subject actually dialling numbers on a telephone linked to the computer, having read a seven- (or 10-) digit number from the monitor screen. A reaction time task is configured to resemble the familiar situation of having to stop and start a car in relation to the colour of the prevailing traffic lights. The effects of certain theoretically interesting variables, such as degree of interference, can also be simulated, for example, by having the subjects hear an "engaged" signal and then asking them to redial the number.

As well as achieving a clear face validity, the battery developed by Crook and his colleagues had a degree of theoretical or construct validity. Recognizing that many of the classical memory batteries, such as the Wechsler Memory Scale[9], in fact have a complex factorial structure including dimensions that can be labelled Attention/Concentration and Orientation, as well as Immediate and General Memory, the battery contains a more comprehensive examination of information-processing capacity that includes, for example, explicit measures of speed of reaction. In addition, evidence for dissociable forms of memory process[10–11] led to the inclusion of tests that probed different aspects of memory.

Although unfortunately this battery no longer appears to be in general use, it was potentially useful in the diagnosis of various age-related memory impairments, including those resulting from Alzheimer's disease, and in the evaluation of candidate pharmacological treatments. It was mainly used to study the relationship between ageing and memory loss in a

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

sample of over 3000 healthy normal subjects in the USA[6]. This study revealed some interesting differences among the tests. For example, the name–face association task administered to 1547 individuals showed a decade-by-decade decline in performance beginning in mid-life, whereas a facial recognition paradigm revealed decline only in the 70+ group in another survey of 326 subjects. Moreover, in the latter study, performance was most impaired at a delay interval of 0 seconds, suggesting attentional rather than mnemonic dysfunction.

The most important theme of the Everyday Memory Battery, which still makes it of contemporary interest, is its adherence to the principle of ecological validity—cognitive functions are tested in the context of everyday functions, which makes them relevant to patient and clinician alike. This is clearly an important element of assessment, but it should also be pointed out that it may be at the expense of test sensitivity, inasmuch that patients can resort to a greater extent on well-learned routines, to overcome deficits that would be exposed by more abstract or unfamiliar test material. In this sense the following two batteries to be considered place less weight on ecological validity and more on theoretical issues, such as the nature of the brain systems damaged in dementia, as well as on practical considerations that enhance the sensitivity and stability of the results obtained.

CANTAB (CAMBRIDGE NEUROPSYCHOLOGICAL TEST AUTOMATED BATTERY)

CANTAB was developed by a group including Dr T. W. Robbins at the University of Cambridge and Dr B. J. Sahakian (Section of Old Age Psychiatry, Institute of Psychiatry) from a research programme funded by the Wellcome Trust to improve the comparative assessment of cognition from animals to humans. CANTAB is a set of computerized neuropsychological test batteries with three main components[4,13]:

1. *Visual memory*. Consists of short pattern and spatial recognition memory tests, a simultaneous and delayed-matching-to-sample test, and a test of paired-associate, conditional learning of pattern–location associations[14].
2. *Attention*. Consists of tests of intradimensional and extra-dimensional set-shifting (analogous to the Wisconsin Card Sorting Test), a reaction time-based visual search task for conjunctive features, according to the Sternberg paradigms[15], and a test of sustained attention, termed rapid visual information processing.
3. *Spatial working memory and planning*. Consists of tests of spatial span, spatial working memory and a computerized version of the Tower of London task, which includes separate measures of thinking and movement time[16].

Each battery employs a touch-sensitive screen and begins with preliminary tests of sensorimotor function, which enable subjects with marked visual or motor deficits to be screened out from subsequent testing. The theoretical rationale for the tests is based on two major themes: first, those animal tests of cognitive function (e.g. delayed matching to sample, spatial working memory and the attentional shifting task, which is based on animal learning theory) that have proved useful in establishing the neural substrates of certain types of cognitive function and can be adapted appropriately for human subjects; and second, a componential analysis of cognitive function, allowing the characterization of elementary processes contributing to cognition. This is exemplified in each battery, e.g. visual memory, where there are separate tests of spatial and pattern recognition memory, as well as a test in which patterned information has to be remembered in specific spatial contexts. In the attentional battery, the attentional shifts are preceded by stages establishing the subject's capacities for simple rule use, acquisition of a simple rule (simple discrimination), its reversal, and its application to more complicated stimuli with additional perceptual dimensions. In the planning battery, some of the componential cognitive requirements for the Tower of London planning task itself, such as the capacities of subjects to remember and use a short spatial sequence, and to employ working memory in a strategic spatial search task, are separately measured. In addition, a "yoked motor control" is employed, which allows the computation of thinking time, corrected for any problems of movement that inevitably confound the interpretation of latency measures in brain-damaged and elderly subjects[16–17]. This yoked control is available to capitalize on some of the advantages conferred by computerized testing; the exact sequence of moves that a patient uses in attempting to solve a problem is stored on-line, and played back to him/her one at a time, in the yoked control test.

The "componential" approach also has some more practical benefits. For example, each test, in addition to containing internal controls, begins at a simple level, so that virtually all subjects achieve a score above floor levels. Moreover, if successful, a subject proceeds to difficult versions of the same test, which avoids ceiling effects. In addition, as the tests are non-verbal in nature, they avoid problems posed by specific language disorders and by illiteracy, and this also makes the tests suitable for cross-national studies. Finally, the tests are available for the IBM machines or similar clones running under WINDOWS '95 or later, which are relatively inexpensive as well as portable (in fact, CANTAB can be implemented on a portable computer equipped with a touchscreen) and so can be used by moderately equipped clinical neuropsychology departments of hospitals, as well as for testing in subjects' or patients' homes[4,13]. The tests are both comprehensive, in terms of the range of cognitive functions they cover, and also sensitive to deficits in patients with dementia of the Alzheimer type (DAT), Parkinson's disease (PD), Huntington's disease and dementia of the Lewy body type[14–20]. Some of the deficits have shown double dissociations across these groups. For example, PD patients show deficits on matching-to-sample, independently of delay, whereas patients with DAT exhibit a delay-dependent decline in performances. In addition, DAT patients early in the course of the disease can perform better than non-medicated, early-in-the course patients with Parkinson's or Huntington's diseases in tests of attentional shifting[15,18,19]. These results are important in showing different profiles of deficits in different forms of neurodegenerative cognitive disorders, which may prove important in the early detection and diagnosis of neurodegenerative diseases and for establishing the neural substrates of the early forms of dementia. For example, it seems likely that the impairments in visual recognition memory that occur early in the course of DAT may reflect temporal lobe deficits, whereas the impairments in attention shifting in unmedicated Parkinson's disease[15] and Huntington's disease[19] may depend upon fronto-striatal forms of dysfunction. Other studies have confirmed that the spatial working memory and planning tests, as well as that of attentional shifting, are sensitive to frontal (but not temporal) lobe damage in humans[16,21].

In the assessment of dementia the results are important because the computerized tests may prove to be more sensitive to cognitive decline than many of the existing instruments, e.g. Mini-Mental State Examination (MMSE)[22] and clinical stagings of dementia[23]. Follow-up testing in populations of DAT and elderly depressed patients with the visual memory battery has shown that many of the tests are sensitive to the effects of progressive intellectual decline in the DAT patients and to the effects of recovery in the depressed group[24]. Some studies have provided evidence that one of the CANTAB tests (paired

associate learning) is capable of discriminating between those patients with questionable dementia that go on to be diagnosed with DAT, and those that do not[25,26]. There is evidence that some of the tests are sensitive to drug treatments in DAT patients[27], as well as to the effects of a variety of drugs in normal subjects, including those that may provide models of different aspects of dementia[28,29].

CANTAB has also been subject to several forms of validation-testing. There are, for example, data on test–retest reliability showing that most of the tests fall into categories described as "good" or "fair"[30–32], even though many tap "fronto-executive" functions that are notoriously unreliable in terms of measurement in this context. Most of the elements of the CANTAB battery have been administered to a large sample of normal subjects (4800) from the North East Age Research Panel. This has resulted in two major publications, which have provided a standardization of the test scores across a wide range of ages and several levels of intelligence[33,34]. There are also burgeoning data on developmental norms[35]. CANTAB is also validated in theoretical terms, partly from the studies of so many patient groups, including those with specific damage to different regions of the neocortex[16,21,36]. There is also a parallel CANTAB battery for testing monkeys, which potentially provides one way of achieving a vertical integration of findings across species[37]. Further data on the underlying neural substrates of the tests is provided via the availability of functional imaging data (mainly derived from positron emission tomography) that confirm which neural networks are activated by different tests[38–42].

COGDRAS: A COGNITIVE PERFORMANCE BATTERY

The Cognitive Drug Research Computerized Assessment System (COGDRAS) is rather complementary to the other two batteries described, in that it is based more on pragmatic considerations of assessing such functions as reaction time and elementary aspects of memory than on theoretical preoccupations with the ecological validity or the relationship of task performance to functional brain circuitry. COGDRAS was originally designed by Dr Keith Wesnes[43] to evaluate the cognitive effects of drugs in normal volunteers and patients. A further version of the battery (COGDRAS-D) was developed to examine cognitive performance in people with dementia[43,44]. In COGDRAS-D eight cognitive tests are presented to the subject, the system originally having been installed on a BBC microcomputer[43]. The subject faces the screen with two index fingers resting on two response buttons. All material is presented visually on the screen in large bold type. The tests comprise immediate and delayed verbal and picture recognition, a test of sustained attention similar to that used in CANTAB, simple and choice reaction time tests, and a memory scanning task. The battery deliberately sets out to avoid problem-solving tasks or the provision of negative feedback. In various extensions of the battery, tests of motor control are also incorporated. Like CANTAB, it has been employed in a wide variety of applications, especially for testing effects of drugs[45] or potential environmental toxins in normal subjects.

One validation study[44] for the dementia version of the battery has assessed 98 unselected patients from a memory clinic, who were divided into five groups on clinical assessment, including demented, depressed, "worried well", minimally cognitively impaired, and other brain disorders. The battery discriminated between some of these groups. In the key comparison of dementia and minimally impaired patients, 6/14 measures were significantly worse than for the demented group, although the level of significance obtained for these individual measures was less than that achieved by the MMSE. It has also been used to compare patients with DAT and Huntington's disease[46]. An earlier study[43] showed good test–retest reliability coefficients for demented patients, particularly on the reaction time measures and significant correlations with other commonly-used instruments in dementia research. More recent applications of the battery have also shown that it is possible to test DAT patients over as long as a 4 h period, in the context of studying the effects of the benzodiazepine antagonist flumazenil[47].

CONCLUSIONS

The batteries reviewed above, as well as others, will ultimately have to be compared with one another, as well as with more conventional assessment procedures, and this will require large and dedicated studies, some of which are under way. A clinician anxious merely to diagnose DAT and other conditions will understandably enquire why such complex tests should supplant the use of such simple and easy-to-use instruments as the Mini-Mental State Examination[22]. The answer is that they are not intended to supplant, but rather to augment, their use. In our own experience, for example, the Mini-Mental State Examination often fails to detect the early onset of dementia, especially in individuals of high IQ. To understand the relationship between such clinical rating scales and the specific computerized tests is to consider the scale as providing a gross measure on a relatively undifferentiated range of functions, whereas the computerized tests provide more specific and precise information about particular capacities, thus providing important information for patient management.

Crook *et al.*[6] pointed out that they found it useful to develop in parallel their own self-rating scales for memory, although the relationships with direct performance measures are typically low. Of course, such low correlations may reflect the measurement of subtly different components of memory, all of which should be taken into account. They view self-rating data as important in assessing age-related memory disorders and family ratings and clinical scales as useful in the assessment of dementia. Certainly, it is important to relate what may be a statistically significant and consistent effect of a treatment on computerized tests of cognitive performance to the clinical improvement manifest to the patient's family in their everyday activities. However, it should be noted that such assessments of everyday activities have not so far proved to be especially discriminating for patients with mild DAT. It is particularly important to add some assessments of everyday activities to the assessments provided by CANTAB and the COGDRAS battery, as these are not specifically designed to simulate such situations. The rationale is that the use of rather visual abstract material tends to be more sensitive in detecting deficits than the use of concrete examples, as there is every indication that many well-established skills (e.g. reading) or types of knowledge (skills) may remain largely intact in early dementia. Moreover, obvious differences in life experience, e.g. produced by different occupations, will tend to be minimized. Finally, we should point out that it is important that batteries such as CANTAB, and to a lesser extent CDR, can provide means for differentiating cognitive disorders in the elderly arising from a variety of conditions, preferably on a qualitative basis. Providing a profile of which functions are spared as well as which are impaired may have implications for strategies based on rehabilitation, as well as pharmacological treatments, which will increasingly motivate attempts at cognitive remediation for the elderly.

The Assessment of Depressive States

Thomas R. Thompson and William M. McDonald
Emory University School of Medicine, Atlanta, GA, USA

The diagnosis of depressive states in the elderly requires a multi-dimensional approach and should not be undertaken without a clear understanding of the normal aging process and the psychosocial factors that are unique to the elderly. The accurate assessment of depressive disorders in the elderly is essential, since this population is often subject to more adverse side effects from pharmacotherapy, and concurrent depression can limit compliance with medical treatments and worsen the cognitive decline associated with dementia. Further, depression can adversely affect the clinical course of other medical illnesses and increase morbidity and mortality[1,2]. Depression in late life is not a normal part of aging and is not necessarily more difficult to treat or chronic when compared to depression in younger people[3,4].

A number of authors have drawn attention to the psychosocial stressors that must be taken into account in the diagnosis of depression in the older population and to the high levels of depressive symptoms in the elderly living in the community[5]. Although the prevalence of individuals with major depression may not be as high as for younger subjects in such settings[6,7], the prevalence increases in elderly patients in long-term care facilities and the medically ill[8,9]. Depressive symptoms can lead to accelerated cognitive decline, physical impairment and increased health care costs. The elderly population maintains the highest suicide rate[10,11] so that the social and economic consequences of this disorder are severe.

THE SYNDROME OF LATE-LIFE DEPRESSION

To accurately assess the depressed older adult, the clinician must be aware of the major syndrome encountered in older adults. The major categories of mood disorders outlined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn[12], are major depression, dysthymic disorder (dysthymia) and adjustment disorder (bipolar disorder is discussed elsewhere), which correspond roughly with the International Classification of Diseases 9 (ICD-9)[13] for diagnoses of manic–depressive psychosis, neurotic depression and brief depressive reaction, respectively. The revision of the ICD (ICD-10)[14] has diagnoses of depressive episode and persistent affective state (with a subclassification of dysthymia) that closely approximate the corresponding DSM-IV classifications.

Major depression is distinguished by the severity of symptoms, which may include significant weight loss or weight gain, insomnia or hypersomnia, psychomotor agitation or retardation, diminished ability to think or concentrate, feelings of worthlessness or excessive inappropriate guilt and recurrent thoughts of death or suicide[12]. A melancholic depression (DSM-IV) or severe depression (ICD-10) represents a subtype of major depression that is felt to be preferentially responsive to somatic therapy (i.e. antidepressants and electroconvulsive therapy) and includes symptoms such as a lack of reactivity to pleasurable stimuli, diurnal variation in mood with depression worse in the morning, early morning awakening, psychomotor retardation or agitation, significant weight loss and other factors that may have a bearing on response, including no significant personality disturbance before the onset of a major depressive episode and a previous history of a major depressive episode that may have responded to somatic treatment. In the DSM-IV, depression is sub-typed according to whether the mood disturbance is associated with a seasonal variation (e.g. a temporal relationship between a distinct 60-day period of the year) or psychotic symptoms that are more likely to be mood-congruent (i.e. delusions or hallucinations of a depressive nature). Psychotic depressions may be more common in late life[15].

The DSM-IV now includes a research diagnosis of minor depression. The duration of the episode and the symptoms are the same as major depression. However, in minor depression the number of symptoms required for diagnosis is less compared to major depression. Minor depression is important in the elderly as there is evidence that these individuals have levels of cognitive and functional impairment similar to those who met full criteria for major depression[16].

Dysthymic disorder (dysthymia) is defined as a chronic low-grade depression, which lasts at least 2 years (DSM-IV), or "several" years (ICD-10). Primary dysthymia may occur in older adults due to changing roles and life conditions. Personality styles and the individual's ability to cope with changing life situations may predispose the individual to develop a dysthymic disorder (see Chapters 71, 74). Although certain severe personality disorders are less common in the elderly, long-standing patterns of perfectionism and the need for external gratification can lead to chronic low self-esteem and dysphoria. Dysthymic disorder may also develop secondary to a medical disorder, which leads to chronic debilitation or other psychiatric disorders, such as substance abuse, anxiety disorder or somatization disorder.

The elderly patient may also have to adjust to severe changes in lifestyle and the loss of loved ones. In the DSM-IV, the patient is not classified with an adjustment disorder unless his/her reaction is considered maladaptive and the level of impairment is significantly severe, so as to be greater than what would be normally expected. The ICD-10 outlines similar symptoms under the heading of mild depressive episodes. Several common life events that prove to be stressors in the elderly

include retirement, financial problems, crime rates, physical illness, the death of a spouse and moving to an institutional setting. Whether the elderly subject's reaction to these stressors is classified as a disorder is a clinical judgement. Regardless, the clinician should watch carefully for the development of symptoms of a major depression if the individual's reaction to stress is persistent or severe.

The symptom profile of older patients with depression has also been posited to differ from that of younger adults, and these subjects are more likely to demonstrate hypochondriacal or somatic symptoms. However, Blazer asserts that this issue is confounded by the significant co-morbidity with other physical illnesses, and these factors must be controlled when making such comparisons[3]. Hypochondriasis, or the belief that one has a serious physical illness, is quite different from an older patient's complaints of physical symptoms such as constipation and nausea. In the hypochondriacal patient these complaints are more likely to be long-standing and to fluctuate over time. In the depressed patient, somatic complaints may become severe and delusional. Somatic delusions can be bizarre and unshakeable. Whereas the patient with hypochondriasis is willing to consider a physical cause for the symptoms, the depressed patient is more likely to have a bizarre rationalization for his symptoms that defy logical explanation. The depressed patient is also apt to show a history of neurovegetative symptoms that have become progressively worse over time.

THE PROBLEM OF CO-MORBIDITY

The diagnosis and treatment of major depression in older adults is more often complicated by concomitant medical illness and/or cognitive decline than in their younger counterparts. For example, over 10% of patients who are initially diagnosed with dementia were found to have an affective disorder when seen in follow-up[17–19]. This misdiagnosis is due to the fact that the symptoms seen in dementia, such as withdrawal, diminished ability to think and concentrate and psychomotor retardation, occur in both dementia and depression. In fact, over 50% of patients with dementing illnesses such as Alzheimer's disease may also have depressive symptoms, with 20% meeting criteria for a major depressive episode[20].

Alexopoulos *et al.*[21] demonstrated that a significant minority of individuals with depression and reversible cognitive deficits eventually progress to true dementia within 3 years. Krishnan *et al.*[24] found an association between apolipoprotein E–e3/e4 (which has been linked to Alzheimer's disease[22,23]) and major depression in later life, further supporting the association of dementia and late-onset depression[24].

Various clinical studies have shown that depressed older subjects are less likely to demonstrate depressed mood[25] or guilt[26] and more prone to complain of fatigue[27]. Other researchers emphasize that these differing presentations are the result of accompanying dementia and medical illness that are more likely to occur in older depressed patients, and that depressed elderly patients without concomitant medical illnesses have presentations similar to younger subjects[28].

Support for this latter view has been provided by Blazer and his colleagues[29], who compared depressive symptoms in a group of middle-aged (35–50 year-old) and older (>60 years) inpatients with melancholic depression. The symptom profiles of these patients were markedly similar to the elderly, differing only in their more frequent reporting of weight loss and less frequent suicidal thoughts. Finally, Blazer discusses some of the misconceptions of depression in the elderly, pointing out that as discussed above, symptomatically there is little difference when compared to adult early-onset depression.

TAKING A HISTORY FROM THE DEPRESSED OLDER ADULT AND FAMILY

The key elements in the patient's history include evidence of a previous psychiatric illness especially a major depressive or manic episode, particularly if that episode responded to somatic therapy (e.g. lithium, antidepressants or electroconvulsive therapies). Obtaining pharmacy and other medical records regarding the symptoms, dose and the duration of medication trials can further aid in the assessment of depressed individuals. Major depression is a recurrent illness, with about half of the patients experiencing two or more episodes in their lifetime. In order to distinguish dementia from depression, researchers have relied upon the findings in the family and individual histories, mental status and laboratory examinations. Determining the time of onset of the depressive symptoms may also be useful, since most dementias are slowly developing, with early evidence of cognitive decline (e.g. the inability to balance a checkbook) being present months to years before the typical form of the disease becomes apparent. In contrast, the course of depressive illness may seem more abrupt.

An accurate family history may also provide valuable diagnostic information, since dementing illnesses (e.g. Huntington's chorea and Alzheimer's disease, particularly the early-onset form) and major depression (especially the early-onset form) have both been demonstrated to have a genetic diathesis. The family history should also include questions about neurological and medical disease, alcohol/drug abuse, anxiety, suicide and psychosis, since these conditions are often associated with concomitant depression.

THE MENTAL STATUS EXAMINATION

The mental status examination and standardized depression rating scales may also aid in determining whether the patient has depression, dementia or (as is often the case) both.

The depressed patient approaches the mental status examination with the same lack of interest that is also apparent in other areas of his/her life. The depressed patient may attempt to prematurely terminate the interview or consistently refuse to try and answer questions. On the other hand, the demented patient may be quite concerned about his/her declining cognitive skills and, at the same time, make attempts to cover their deficits with confabulation[30]. He/she may use notes and other reminders to keep up with facts and uncovering his/her deficits might be quite distressing. This is in marked contrast to the apathetic attitude of the depressed patient. The depressed inpatient is also more likely to be able to find his/her way around the ward and to keep track of the ward routine and personnel. In contrast, the demented patient will forget mealtimes and confuse familiar faces. This confusion may often get worse as evening approaches and is incorporated in the well-known clinical syndrome of "sundowning".

The mental status examination of patients with physical illnesses may show primarily problems with concentration and attention. In more severe cases, evidence of delirium may be present. Delirium is diagnosed when the level of consciousness becomes impaired. In this condition, disorientation and memory impairment may be present along with illusions (which are misinterpretations of environmental stimuli), hallucinations and disturbances in psychomotor activity and the sleep–wake cycle. As opposed to dementia, these symptoms usually evolve over hours and days rather than months and may show a waxing and waning course along with autonomic instability.

A common clinical dilemma occurs in patients who are known to be demented, but in whom the clinician seeks to make an accurate diagnosis of depression. In these patients, the clinician may need to assign more weight to neurovegetative signs, such as weight loss

and insomnia, although these same symptoms may occur in non-depresssed demented patients if they are too disorganized to prepare a meal or have night-time confusion. Some researchers have pointed to the presence of cognitive symptoms of depression (i.e. depressed mood, anxiety, helplessness, hopelessness and worthlessness) as being more prominent in demented patients, whereas neurovegetative signs are notably absent[31].

Monitoring the patient over time, observing for some overall consistent pattern of depressed mood and affect, is also helpful. Although there is little or no data to support empiric trials of antidepressants, given the relatively low side-effect profile of the newer antidepressants[32] (SSRIs: see Chapter 78), many clinicians will often attempt a trial of an antidepressant in these difficult situations in hopes the treatment may improve cognition and function.

PSYCHOLOGICAL TESTS

Standardized assessments of cognitive performance (e.g. Wechsler Adult Intelligence Scale and Clinical Dementia Rating Scale[33]) may also be useful in distinguishing depression and dementia. The depressed patient will more likely show results that are inconsistent over time and are effort-dependent. The demented patient will demonstrate a more global decline, with relatively lower scores on aspects of the testing requiring adaptability and processing of information (e.g. performance IQ) as opposed to rote skills and long-term memory tasks (e.g. verbal IQ).

Standardized depression scales may yield false-positive results in demented patients, particularly if they are heavily weighted for difficulties symptoms, such as with attention and concentration, which overlap with symptoms of depression. Depression scales that have been specifically designed to grade levels of depression in patients known to be demented include the Cornell Depression Scale[34] and the Dementia Mood Assessment Scale[35]. The Geriatric Depression Scale (GDS), Beck Depression Inventory (BDI) and the Montgomery–Asberg Depression Rating Scale (MADRS) are other useful tests that can help aid in evaluation of a depressed patient[36–38].

LABORATORY TESTS

The common laboratory tests for depression may lose much of their specificity in demented patients. The Dexamet has one suppression test that is frequently abnormal in dementia[39,40].

The sleep electroencephalogram, however, does maintain its specificity and is able to distinguish a group of elderly depressed patients from those with dementia[41,42].

Any physical illness that can potentially affect the central nervous system can present with depressive and dementing symptoms; these illnesses include encephalitis, chronic subdural hematoma and normal pressure hydrocephalus. Depressive symptoms such as fatigue, insomnia, weight loss and concentration problems can occur in other illnesses that do not directly affect the central nervous system (CNS). These illnesses include infectious diseases (e.g. tuberculosis, influenza), cardiovascular disease (e.g. congestive heart failure), endocrine abnormalities (e.g. thyroid disease, diabetes), electrolyte disturbances (e.g. hyponatremia, hypocalcemia), renal and hepatic disease.

Recent evidence has indicated that both cerebral vascular accidents and periventricular[42] white matter disease are related to depressive symptoms in the elderly[44,45].

MEDICAL WORK-UP

Medical conditions also present with depressive symptoms in the elderly. Many of these medical conditions are reversible with proper treatment, and estimates of the number of patients with reversible conditions presenting as dementia have been as high as 15%[17]. The work-up of medical conditions that present with depressive symptoms in the elderly includes a personal history of medical illness, mental status examination and laboratory tests[46].

The physical examination and laboratory diagnosis is crucial in the diagnosis of medical disorders. The typical laboratory screening for elderly patients with depressive symptoms is outlined in Table 29.1. Clearly, the medical history and physical examination would influence the laboratory testing that was actually done. The neurologic examination should be particularly thorough and include an examination of both subtle (e.g. frontal reflex signs) and prominent (e.g. reflex changes) signs of neurologic dysfunction.

Table 29.1 Laboratory work-up in the depressed elderly patient

Laboratory test	Underlying condition
Complete blood count	Infectious disease
	Encephalitis
	Meningitis
	Sub-acute bacterial endocarditis
	Anemia
Electrolytes	Hypokalemia
	Hyponatremia
	Diabetes
	Uremia
B_{12}/Folate	Pernicious anemia
Thyroid panel	Hypo/hyperthyroidism
Liver enzymes	Hepatitis
	Liver cancer
Calcium/phosphorus	Hyperparathyroidism
Guiaic stool	Colon disease
Urinalysis	Infection
	Renal disease
Consider additional test including: Electrocardiogram	Particularly patients who complain of fatigue, edema, shortness of breath or who are being considered for antidepressant therapy
Electroencephalogram	When delirium may be a concern or to screen for a mass lesion
Urine drug screen	For lead (exposure to paint), mercury (textile manufacturing), organophosphates and arsenic (insecticides). Also drugs of abuse (e.g. opiates, marijuana, etc.)
Human immune deficiency virus (HIV)	Exposure to potentially contaminated blood products (surgery, drug use) or a history of promiscuity or homosexuality
Brain computed tomography	Neoplasia, stroke
Brain magnetic resonance imaging	Particularly to view the posterior brain stem

MEDICATION HISTORY

Medication, including the antihypertensive medications such as propranolol and centrally acting α-methyldopa and reserpine, has been shown to cause depressive symptoms. Drugs such as alcohol are also frequent causes of depression in the elderly, as are the barbiturates that are used as sedatives. Patients at risk should be screened for heavy metals, including lead, arsenic and the organophosphates.

SUMMARY

Depressive symptoms are common in the elderly, whereas the syndrome of a major depressive episode is relatively rare[6,45].

Symptoms of depression can be manifestations of either dementing or medical illnesses, both of which are common in the elderly. Psychosocial factors that are unique to the elderly may be etiologic in the genesis of depressive symptoms, but nevertheless require the clinician to assess each patient fully and treat as appropriate. Accurate treatment mandates as detailed history, often with collaboration with the family, and a thorough medical evaluation for other co-morbid illnesses that may contribute to the patient's current presentation. The treatment of depressive symptoms in the elderly requires an understanding of both the origin of these symptoms and the proper treatment of the underlying disorder, whether it be due to medical, dementing, psychosocial or melancholic factors.

The Geriatric Depression Scale: Its Development and Recent Application

Ruth O'Hara[1] and Jerome A. Yesavage[2]

[1]*Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, CA, and* [2]*Veterans Administration, Palo Alto Health Care System, CA, USA*

Developed in 1983, the Geriatric Depression Scale (GDS) is a 30-item self-report measure for rating depression in elderly adults[1]. The identification of depression in older adults is of particular importance to clinicians, since depression is the most common psychiatric disorder in this population and can be associated with morbidity and mortality[2].

The GDS was designed to address the unique characteristics of geriatric depression and the subsequent difficulties in rating depression in older adults using scales developed for younger populations. Somatic complaints are less useful indicators of depression in the elderly than in young adults, since such symptoms often accompany the normal aging process. Depression in older adults is more often accompanied by subjective complaints regarding decline in memory and cognition than is depression in younger adults. Questions pertaining to suicidal intent or one's hopefulness regarding the future can be interpreted differently by elderly adults, who are in the latter stages of their lifespans. To address these issues, the GDS excludes questions pertaining to somatic complaints, registers a cognitive dimension of depression and focuses dominantly on the worries of the individual and how that person interprets his/her quality of life. Additionally, the GDS employs a yes–no format for both economy of time and ease of self-administration in this population.

The scale was developed and validated in two phases. First, 100 widely varied yes–no questions were selected and tested for their potential to distinguish depressed elderly adults from normal controls. The 30 questions correlating most highly with depression were chosen for inclusion in the final version of the GDS. Second, validity of the scale was established by comparing the mean GDS scores for subjects classified as normal, mildly depressed or severely depressed, using the Research Diagnostic Criteria (RDC) for depression. The mean GDS scores for these three groups were reliably different and were ordered in accordance with the differing RDC scores[1]. The scale has been found to have high internal consistency and high test–retest reliability. A score of 11 or higher has been found to indicate the presence of depression, yielding 84% sensitivity and 95% specificity[3].

The GDS has been utilized widely in clinical practice and research and has been shown to be a reliable and valid measure of depression in outpatient, nursing home and hospital settings[4–6]. Additionally, the GDS is sensitive to depression among elderly adults suffering from mild to moderate dementia and elderly adults with physical illnesses[7].

To date, the GDS has been translated into 21 languages, including Spanish and Chinese. It is in the public domain, and available on the Web (http://www.stanford.edu/~yesavage/GDS.html). A 15-item, short form of the GDS has been developed and validated[7]. Additionally, administrations of the GDS by telephone and by requiring caregivers to answer the questions have been validated[8,9].

Overall, the GDS provides a sensitive measure of depression in older adults that is time-efficient, easy to administer and reliable and valid in a broad range of clinical and research settings.

Center for Epidemiologic Studies Depression Scale: Use among Older Adults

Dan G. Blazer
Duke University Medical Center, Durham, NC, USA

The Center for Epidemiologic Studies Depression Scale (CES-D) is a depression screening instrument which has been applied widely in epidemiologic studies including many community-based studies of older adults[1–3]. The scale consists of 20 items which on factor analysis among older adults fall into four different factors. The first factor is depressed affect, and items that load on this factor include: "bothered by things that usually don't bother me", "I could not shake the blues", "I felt depressed", "I felt lonely", "I had crying spells" and "I felt sad". The second factor is positive affect and includes the items: "I felt as good as other people", "I felt hopeful about the future", "I thought my life had been a failure", "I was happy" and "I enjoyed life". The third factor is somatic complaints and includes the items: "I did not feel like eating", "I had trouble keeping my mind on what I was doing", "My sleep was restless", "I felt like everything was an effort", "I talked less than usual" and "I could not get going". The final factor is interpersonal relations and includes the items: "People were unfriendly" and "I felt that people disliked me". Each item is rated on a 1–4 scale, depending on the frequency of symptoms the week prior to the administration of the scale. Therefore, the range of answers is 0–60. A score of 16 or greater is considered indicative of clinically significant depression[1].

Murrell *et al.*[4] found, when using the CES-D in a community of over 2000 community-dwelling adults, 55 years of age and older in Kentucky, that the mean score was 8.9 for African-Americans and 9.2 for Whites. When they applied the cut-off noted above for clinically significant depressive symptoms, 12.8% of African-Americans and 13.7% of Whites had clinically significant depression[4]. Berkman *et al.*[5] found that 16% of both African-Americans and Whites in an urban community scored above the threshold for clinically significant symptoms. When control variables are taken into account, such as gender, socioeconomic status and functional health, the association of age and depression disappears (whereas in uncontrolled analysis there is a positive association between age and depression) using the CES-D[6].

When using the CES-D in older adults, there is little difference by gender and little difference by race/ethnicity[2]. In a cross-sectional analysis, age is negatively associated with somatic complaints, lower education is associated with more complaints of depressed affect and interpersonal problems, African-American race is associated with increased interpersonal complaints and cognitive impairment associated with somatic complaints and interpersonal complaints. Of all control factors, however, disability is most closely associated with all four of the factors noted above.

In summary, the CES-D is a useful screening scale for depressive symptoms in community (and clinical) samples of older adults. The one drawback to this scale is that it requires responding along a spectrum of four responses (little or none, some of the time, most of the time, or all the time) over the previous week compared to a simple yes–no format, as is found in other symptom screening scales. The scale has been used extensively in older adults and therein lies its greatest value for future epidemiologic studies as well as clinical screening efforts.

The Development of the EURO-D Scale

Martin Prince

Institute of Psychiatry, London, UK

BACKGROUND

The 11 country EURODEP consortium, assembled an unprecedented body of data; 14 population-based surveys of mental health in late life, including 21 724 older Europeans aged 65 years and over. Most centres had used either GMS/AGECAT[1] or the very similar SHORT-CARE[2] as their index of clinical case-level depression. However, three centres had used the Centre for Epidemiological Studies Depression scale (CES-D)[3], one the Zung Self-rating Depression Scale (ZSDS)[4] and one the Comprehensive Psychopathological Rating Scale (CPRS)[5]. Our challenge, therefore, was to derive from these instruments a common depression symptom scale, allowing risk factor profiles to be compared between centres[6].

METHOD[6]

The instruments were scrutinized for common items. Algorithms for fitting items from other instruments to GMS were derived by either: (a) empirical observation of the nature of the relationship between items in different scales where they had been administered together; or (b) expert opinion. The resulting 12-item scale (see Table 30.1) was checked in each centre for internal consistency, criterion validity and uniformity of factor analytic profile.

RESULTS[6,7]

The EURO-D, however derived, is an internally consistent scale. Cronbach alphas for the 14 centres ranged from 0.58 to 0.80. It seemed also to capture the essence of its parent instrument. Correlations with the CES-D in all four centres using that measure exceeded 0.90, and the correlation with the Zung was 0.84. A cut-point of 3/4 on the EURO-D scale predicted a GMS/AGECAT computerized diagnosis of depression with 70–80% sensitivity at 80–95% specificity. Principal components factor analysis demonstrated that a very similar two-factor solution seemed appropriate in all centres, however the scale had been derived; depression, tearfulness and wishing to die loaded on the first factor (affective suffering) and loss of interest, poor concentration and lack of enjoyment on the second (motivation).

In general, EURO-D scores increased with age, women scored higher than men, and widowed and separated subjects higher than others. The gender effect was negligible among the never-married but was not modified by age. In most centres EURO-D could be reduced into two well-characterized factors; affective suffering, responsible for the gender difference, and motivation, accounting for the positive association with age.

CONCLUSIONS

Large between-centre differences in depression symptoms as assessed by EURO-D were explained neither by demography nor by the depression measure used in the survey. Consistent, small effects of age, gender and marital status were observed across Europe. Depression may be overdiagnosed in older persons

Table 30.1 EURO-D Scale.
The Geriatric Mental State (from which EURO-D is derived) is a semi-structured clinical interview. The following instructions apply:
1. Each question should be asked as it is written. The sections in parentheses are additional prompts to clarify the question if it has not been understood.
2. Sections in *italic* script provide the criteria by which the interviewer judges from the response whether the symptom is present or absent.

EURO-D item		Corresponding GMS question
1.	Depression	Have you been sad (depressed, miserable in low spirits, blue) recently?
2.	Pessimism	How do you see your future? *Pessimistic, empty expectations or bleak future*
3.	Wishing death	Have you ever felt that you would rather be dead? *Has ever felt suicidal or wished to be dead*
4.	Guilt	Do you tend to blame yourself or feel guilty about anything? *Obvious guilt or self blame*
5.	Sleep	Have you had trouble sleeping recently? *Trouble with sleep or recent change in pattern*
6.	Interest	What is your interest in things? *Less interest than is usual*
7.	Irritability	Have you been irritable recently?
8.	Appetite	What has your appetite been like? *Diminution in the desire for food*
9.	Fatigue	Have you had too little energy (to do the things you want to do)? *Listlessness or subjective energy restriction*
10.	Concentration	How is your concentration? *Difficulty in concentrating on entertainment or reading*
11.	Enjoyment	What have you enjoyed doing recently? *Almost nothing enjoyed*
12.	Tearfulness	Have you cried at all?

because of an increase in lack of motivation that may be affectively neutral, and is possibly related to cognitive decline.

The EURO-D scale shows promise as a means of harmonizing data from studies and perhaps trials that have used similar depression outcome measures. In the EURODEP datasets the EURO-D has been used informatively in three ways[7]:

1. To compare EURO-D item prevalence between centres.
2. To compare EURO-D scale distribution between centres.
3. To compare effect sizes for associations between risk factors and EURO-D score between centres.

Researchers might consider using the EURO-D in epidemiological or health services research, either on its own or as a component part of the GMS. Its principal advantage at present is the large amount of normative data available from the many population-based studies in different parts of the world to have used the GMS. A limitation of the scale is its current format, which relies upon interviewer administration and rating. A future priority will be to develop self-report forms and test their equivalence against the current version.

Interviews Aimed at Differential Psychiatric Diagnosis

GMS–HAS–AGECAT Package

John R. M. Copeland

Department of Psychiatry, Royal Liverpool University Hospital, UK

For epidemiological and other studies of mental illness and morbidity in older age it is important to ensure as far as possible that the differences in the levels of cases of illness found between geographical areas and between studies at different points in time are not due to methodological differences and, in particular, the way the diagnoses themselves are made. To overcome this problem, standardized interviews were introduced. The GMS–HAS–AGECAT Package consists of a series of interviews designed to be given to a subject and his/her informant for assessing the dementias and depression, with optional sections for minor mental illness[1,2]. The Geriatric Mental State (GMS) was derived originally from the Present State Examination[3] and the Mental Status Schedule[4]. Substantial modifications and additions were incorporated to make it more applicable to older populations and to increase emphasis on organic states. The Package now provides, in addition to the GMS, which is an interview with the subject, the History and Aetiology Schedule (HAS) for an informant, which allows the assessment of onset and course of illness, past history, family history and certain risk factors for dementia, depression and other mental illness. The Secondary Dementia Schedule provides a semi-structured framework to aid in collecting information required for the NINCDS–ADRDA (National Institute of Neurology and Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders Association) criteria[5] and the assessment of daily living.

Standardization of diagnosis is achieved by the AGECAT (Automated Geriatric Examination for Computer Assisted Taxonomy) computer-assisted differential diagnosis[6–8]. Based on an extensive decision tree method, the system aggregates the data into scores and allots each subject to levels of diagnostic confidence on each of eight diagnostic syndrome clusters, organic, schizophrenia/paranoid, mania, depression (psychotic and neurotic type) (levels 0–5), obsessional, hypochondriacal, phobic and anxiety neurosis (levels 0–4). Levels 3 and above are what would usually be recognized by psychiatrists as cases of illness. The computer then compares these levels with one another to derive a final differential diagnosis and flags cases where the decision has been difficult. The validity of the AGECAT diagnosis has been assessed against psychiatrists' diagnoses on the same patients. The range of kappa values for the agreement between AGECAT and psychiatrists' diagnoses for organic states is 0.80–0.88 and for depressive states 0.76–0.80[6]. Outcome studies are now providing additional validation. After 3 years' follow-up, over 83% of AGECAT cases of organic disorder identified in a community study were either dead or still dementing. One-third of depressed cases were also depressed 3 years later[9]. Post mortem validation studies are in progress.

In the second stage AGECAT uses the data from the HAS to take the diagnosis to a further stage, dividing organic states into acute or chronic, and the latter into the different types of dementia using a standardized form of the Hachinski score[10]. It also identifies bereavements and flags coexistent immobility, pain, life-long intellectual function and physical illness.

The GMS can be used by trained lay workers and provides a diagnosis by AGECAT. When used in epidemiological studies it is possible to derive prevalence figures for the full range of psychiatric morbidity using a one-stage design[11]. The measures are therefore economical as well as reliable and valid. The Package does not rely on special psychological tests as these are not applicable across cultures or socioeconomic groups or with populations of varying literacy. The interviews have also been transferred for presentation on laptop computer, which improves accuracy and communication, avoids delays and costs in inputting data, and provides rapid access to results and easy quality control of interviewing techniques[12].

These measures have been used in a number of projects, including the Medical Research Council (UK) ALPHA[13,14] study of the incidence of the dementias and the multicentre Cognitive Function and Ageing Study, the EURODEP EC-funded Concerted Action[16], the ongoing ASIADEP studies in 12 Asian centres and the 10/66 Club studies on the prevalence of dementia in India, Latin America and Africa, as well as forming part of the minimum data set required by the EURODEM (EC Concerted Action on Epidemiology and Prevention of Dementia)[17,18]. The GMS has been translated and used in a wide range of languages. Recently, algorithms have been developed for ICD-10, DSM-III-R and DSM-IV and compared favourably with psychiatrists' diagnoses using these international criteria. The HAS has been shortened and modified to provide for the criteria of Lewy body dementia and other recognized dementia classifications.

CAMDEX

Daniel W. O'Connor

Monash University, Melbourne, Australia

The Cambridge Examination for Mental Disorders of the Elderly (CAMDEX) was devised to assist clinicians and epidemiologists to diagnose dementia, and mild dementia in particular, as reliably and validly as possible[1]. It was developed with the following aims in mind: it addresses all elements of current diagnostic criteria; it incorporates historical material so that persons with cognitive deficits due to intellectual disability, sensory handicap or functional mental disorder are classified correctly; and its neuropsychological battery is sensitive to mild dementia.

The schedule is fully structured and incorporates: a mental status examination; a comprehensive neuropsychological battery (CAMCOG); a medical and psychiatric history; a brief physical examination; and an interview with an informant that enquires into changes in memory, intellect, personality, behaviour and self-care. Medications, laboratory investigations and imaging are all recorded. There is a clear focus on dementia but conditions such as delirium, anxiety, depression, bipolar disorder, delusional disorder and schizophrenia are considered as differential diagnoses. The respondent interview takes 30–60 minutes to complete. Informants are questioned for another 20–30 minutes, by telephone if necessary. Diagnoses are based on all available data using criteria virtually identical to those in ICD-10. Since judgement is required, interviewers should have a clinical background and have received training in formulating complex data, applying diagnostic criteria and rating dementia severity.

CAMDEX, which is available in English, Dutch, French, German, Italian, Spanish and Swedish versions, is practicable and acceptable and can be administered with high inter-observer reliability[1]. It includes the Mini-Mental State Examination[2], Hachinski Ischaemia Scale[3] and other commonly-used rating scales. When applied in community surveys, prevalence rates of dementia based on CAMDEX assessments are close to those reported in other recent Western European studies[4]. CAMDEX diagnoses are also stable over time. In a British study in which community residents rated as having mild dementia were followed for 2 years, diagnoses were maintained for 51 of the surviving 56 persons. Two were re-classified as having minimal dementia and only three were rated as having no significant impairment, mostly as the result of better-controlled diabetes mellitus[5,6]. CAMCOG has been used as a stand-alone assessment package in many clinical and community studies. Further details about its psychometric properties can be found on the website listed below.

An updated version of CAMDEX includes both DSM-IV and ICD-10 diagnostic criteria and provides better coverage of more recently described conditions, such as frontotemporal dementia and dementia of the Lewy body type. A floppy disk permits computer-assisted administration, data entry, scoring and analysis. CAMDEX is copyright but packs including the interview schedule, test materials and scoring sheets can be purchased in most countries. Consult this website (http://www.iph.cam.ac.uk/camdex-r) for further updates, access to a dedicated bulletin board, references to published reports based on CAMDEX and CAMCOG, and other relevant information.

Assessment of Daily Living

Kerstin Hulter Asberg
University of Uppsala, Sweden

The need for assessing activities of daily living[1] (ADL) has increased during the last few decades for several reasons. First, the number of disabled persons in the population is higher today than ever before, since more people survive longer and have to live with the consequences of diseases and other[2] disorders. Second, the costs for ADL-related services to disabled persons have surged ahead, both for sheltered living and for assistance given by people paid to provide services in the homes. Relatives and neighbours will often give voluntary help but they, too, may need professional support. Third, there is a need for outcome measures, other than mortality and morbidity, which can describe levels of function among elderly people. This is required for the evaluation of pharmacological treatments and rehabilitation programmes. Many people in different professions are involved in the care of the elderly, e.g. physicians, nurses, occupational therapists, physiotherapists and social workers. In clinical practice, they need a common language to communicate their knowledge about the individual's functional level. Although much work has already been done to develop new ADL instruments and make existing ADL assessments representative, reliable and valid, much remains to be done to reach a consensus in this field. Even a definition of the concept of ADL can still be a matter for discussion: "ADL" means "activities which are common to all human beings and which must be performed regularly in order to live an independent life". This is a very broad definition, which permits a variety of activities to be included. These activities are usually divided into several categories:

1. *Personal ADL*: activities concerning self-care, care of one's own body, e.g. feeding, dressing, bathing.
2. *Instrumental ADL*: activities concerning home management, e.g. cooking, cleaning, shopping.
(*Communication by talking and writing may be referred to as personal ADL, while transportation and managing money may be referred to as instrumental ADL.*)
3. *Professional work*.
4. *Leisure activities*.

Ambulation or walking is not an ADL item, although it is often assessed in this context. It is rather a level of mobility on a scale from bed-ridden, through unsteady gait such as creeping, to walking and running. A certain level of mobility is usually required for independent living as is a certain level of intellectual capacity, motivation and a suitable environment.

"ADL-capacity" means that a subject can perform ADL independently of another person. Even if a person can do things, it may not be certain that he/she actually does them in practice! In the WHO Classification of Impairments, Disabilities and Handicaps, ADL-dependence is classified as a disability. "Disability" has been defined as "any restriction or lack (resulting from impairment) of ability to perform an activity in the manner or within the range considered normal for the human being"[2].

"ADL-ability" means that a subject does perform ADL. It may take time, it may hurt, or there may be other difficulties, but the person is nevertheless able to perform ADL and independently of another person. If a person does not perform ADL, it may be due to physical or intellectual capacity deficits (he/she can not or does not understand) but it may also be due to lack of motivation (he/she does not want to do it), or to environment problems (he/she is not allowed to do it or is prevented).

When assessing ADL-performance in clinical practice, it is recommended that the interviewer starts with the question: "Does the patient perform the activity or not?" If he/she does not or has difficulties, the interviewer may proceed by asking "Why should this be?" There may be physical, mental and/or social reasons, which then must be analysed in more detail to form the basis for decisions on rehabilitation.

"ADL assessment" is part of the broader concept of "functional assessment", which implies assessment not only of disability but also of impairments and handicaps. "Functional assessment" is to be found in DSM-III-R and in DSM-IV[19] in Axis V. The Global Assessment of Functioning (GAF) scale is a hierarchical assessment scale not only of psychic symptoms but also of social and professional functioning.

The ADL instruments can be constructed as check lists, a summed index or hierarchical scales.

WHAT IS AVAILABLE TO ASSESS ACTIVITIES OF DAILY LIVING?

Many structured ADL assessment instruments have been developed but rather few have been used by persons other than their inventors. Most instruments include the same types of personal items, but they often have divergent operational definitions, if indeed they are defined at all. Some instruments combine personal and instrumental items. There are also multidimensional instruments with ADL items mixed up with those for other assessments, such as mobility, physical status, mental capacity and social conditions.

An overview of such instruments, mainly from Anglo-Saxon countries, is given in Kane and Kane[4]. This field of study is also undergoing continuous and rapid development in other countries, so readers are recommended to check up on the key-word "Activities of Daily Living" in *Index Medicus*.

DIAGNOSIS AND ASSESSMENT

When choosing an ADL instrument, three questions need to be asked:

Question 1: for what purpose is it to be used?

Possible uses could be:

(a) To describe and document any need for assistance in performing ADL.
(b) To differentiate among different levels of disability.
(c) To follow and record changes in ADL performance over time.
(d) To predict outcome, survival, length of hospital care, type and quality of living, etc.
(e) To evaluate rehabilitation programmes, hospital, home and day care, etc.

Question 2: for whom is it intended?

(a) For individuals, for groups with certain medical diagnoses or receiving different types of care or for populations?
(b) For mainly healthy persons or for the mildly or severely disabled?
(c) For patients living in institutions or in their own homes or for patients with or without cognitive impairment?

Most published instruments are shown to be reliable and valid for particular purposes and for particular patient categories. The same instruments may be unsuitable for use in other circumstances, e.g. instruments that include personal items only are often adequate for the more seriously disabled patients living in institutions, whereas instruments including instrumental items are necessary for use with more healthy populations living in their own homes. For patients with serious cognitive impairment, the ADL instrument has to depend on observation or test situations. The assessment has to take into consideration the patient's own dependence on active assistance as well as the patient's dependence on supervision, and whether or not activity is initiated by another person. The quality of ADL performance has also to be assessed; for example, if the patient dresses him/herself independently, does he/she dress him/herself adequately and appropriately for the situation?

Question 3: are the results of ADL assessment expected to be compared with other ADL assessments?

If so, it is necessary to choose an ADL instrument that has been tested and documented as to its reliability and validity for the chosen purpose and the specified patient category. If a group of patients is to be compared with normal subjects, data on nationally representative samples must also be available for comparison.

It may be difficult, if not impossible, to find one ADL instrument to fit all purposes. In any case, it is usually better to choose one of the well-known instruments and then supplement it with items that seem important in that specific situation, than to start the immense work of creating a new instrument. It is also better to use a plain ADL instrument instead of a multidimensional one, if the purpose is simply to study ADL ability.

Time and staff resources are also limiting factors when choosing an ADL-instrument. Self-administered questionnaires are less expensive to administer, but require patients who understand the questions and can respond adequately. The number of subjects who drop out may be high, so some validation of the answers is necessary. This type of instrument is mainly used in studies of elderly general populations, who are expected to be reasonably healthy.

Observations of the patient's actual ADL performance can be carried out during a nurse's daily work, when documentation will take only a few minutes. Training of the observers is usually required, along with tests of inter-observer reliability.

Test situations that use professional observers are the most expensive measures. Even if the test situation does not correspond exactly to real life, it can still be of value for specific purposes, e.g. when occupational therapists analyse the kind of impairment that is hindering performance or how rehabilitation should be undertaken; or in methodological studies, such as in a study of the relationship between severity of dementia and ADL performance[5].

In clinical practice, occupational therapists usually combine self-report information concerning the disabled patient's own values, personal causation, interests, roles, habits and skills with observations and test situations[6].

HOW GOOD ARE THE ADL ASSESSMENTS?

The quality of an ADL instrument depends on the following factors:

1. *Its representativeness*: i.e. whether the items reflect the activities of a person's normal daily life.
2. *Its reliability*: viz. its reproducibility and stability, so that the results can be reproduced by other observers or by the same observer at different times, so that changing results reflect changes in the patient's ADL status.
3. *Its validity*: i.e. whether the results are meaningful to others; whether they can be understood and used to compare with other data reflecting different levels of disability; and whether they may predict outcome.

These aspects of instrument quality are generally easy to test, but the problem is the lack of a norm or gold standard for comparison. The closest approximation to such a norm is the Katz Index of ADL[7], which is based on a cumulative scale of personal items reflecting improvement and deterioration among disabled patients, and designed to correspond with ADL development in the small child.

Other instruments may include more or less the same items as in Katz Index, such as Barthel's Index[8], but problems arise when the authors put arbitrary nominal values on different levels of ADL ability, which are ordinal in character, and then summarize the assessments. The results may be affected by systematic statistical errors, but more importantly they may obscure the understanding of actual ADL status and undermine the possibility for interstudy comparisons using different instruments. For example, if a patient scores 75 out of 100 possible points, this will not reveal in which items the patient is dependent. Furthermore, one patient with 75 points may not be as disabled as another person with an equal number.

Quite another way of handling ordinal data is shown by the development of Katz's Index of ADL. In the 1950s, a multidisciplinary team in Cleveland, Ohio, followed patients who were recovering from a hip fracture by assessing in which order they regained the ability to perform ADL. They found six items that usually followed in sequence: first the patients regained independence in feeding, followed by continence, movement of the body (e.g. getting out of bed), going to the toilet, dressing and bathing. A patient who was independent in bathing could be expected to be independent in the other five items, too, and a person who was dependent in feeding was also dependent in the other items. The authors defined each item carefully, and found that dependence on another person, either by active assistance or supervision, decided whether or not the subject was dependent.

The authors had discovered a hierarchical or cumulative order between these six personal activities of daily life, which formed the beginning of an ADL "staircase" where each step upwards corresponded to an improvement in the patient's condition. Later, it was shown that patients with other diagnoses, such as stroke

and rheumatoid arthritis, and mentally impaired people improved and deteriorated in the same way[9]. The instrument has been used for a number of purposes among elderly and disabled people in many countries[10]. In Sweden, it is used in clinical practice by medical and geriatric departments and in home care to communicate information about the patients' ADL ability. The level of ADL performance has been shown to predict survival and death, length of hospital stay and type of hospital discharge in acute medical care[11,12].

The cumulative order of items was found to correspond to the observations made by Gesell of the ADL development in small children during their first 7 years. This sociobiological origin may explain the good predictive validity of the instrument. The limitation of the scale is primarily a ceiling effect. It does not differentiate among less disabled persons, who are independent in bathing. But the small child does not stop developing at age 7, and the very existence of a cumulative scale evoked the question of what comes after bathing.

From population studies, it was possible to derive scales of percentages of the population with activity limitations. Lawton and Brody[13] formed hierarchical scales of personal and instrumental items. These cumulative ADL items were incorporated in a comprehensive multidimensional scale, the Older American Research and Service Center (OARS) instrument[14]. In order to provide shortened measures, Fillenbaum formed a five-item cumulative instrumental ADL scale out of the OARS instrument[15]. Spector and Katz[16] reported that the instrumental items of cooking and shopping were ranked higher than personal items. From the Gothenburg population study[17], ADL reduction was found in about 30% of 70 year-old people, mostly due to dependence in the personal items of the ADL.

To understand further the cause of disability in old age, it was necessary to formulate exact definitions for instrumental activities, which could be ordered into an extended cumulative scale. Sonn and Hulter Asberg[18] found that the items of cooking, transportation, shopping and cleaning could be defined and ordered next to bathing in Katz's Index of ADL. The ADL "staircase" now consists of 10 items: feeding, continence, movement of the body (e.g. getting out of bed), going to the toilet, dressing, bathing, cooking, transportation, shopping, cleaning. This ADL staircase can be used for observation and documentation of the different levels of disability for individuals, groups of patients and for population studies. For individuals, it can be supplemented by test situations according to the occupational therapists' assessment of the need for rehabilitation. For groups of patients, it can be supplemented by disease- or symptom-specific scales, and populations can be assessed by interviews, where the interviewer also assesses whether or not the answer seems a reasonable one.

There may be special reasons for choosing other ADL instruments than the one described above, such as historical reasons, instruments that include more items and are more sensitive to small changes in disability and that offer the possibility of comparison with earlier studies. Furthermore, important research work by occupational therapists is now in progress, attempting to develop special ADL instruments for patients with psychiatric problems. The field is, as it were, "preadolescent". In order to achieve a general standard for ADL assessments, it would be valuable to use the ADL staircase alongside other instruments. This would facilitate comparisons between different studies and help promote knowledge about, and understanding of, the ADL status of elderly patients.

Rating Scales Designed for Nurses and Other Workers

Kenneth C. M. Wilson, Ben Green and P. Mottram

Department of Psychiatry, University of Liverpool, UK

The changing role of nurses and other workers in the context of clinical audit and community care has provided a fertile backdrop for the development of brief and easy-to-use clinical rating instruments. Few of these are of diagnostic validity and they require little or no training. The are usually employed to rate clusters of signs, symptoms, syndromes, behaviours or needs. They have often been developed from other instruments or through clinical observation. The majority have been exposed to validation and inter-rater reliability and some are furnished with "cut-off" scores corresponding to external diagnostic criteria. Nurses and other professionals have been successfully trained in the delivery of more complex diagnostic and assessment instruments, including CAMDEX and GMS. However, this chapter will focus on relatively brief clinical instruments requiring little or no training, primarily designed for nurses and carers. This chapter is by no means exhaustive but is designed to provide an overview in a rapidly developing field.

ORGANIC STATES INCLUDING DEMENTIA

Some of the specialized neuropsychological instruments, including the Kendrick Battery, are usually carried out by psychologists and have been extensively validated[1]. However, there now exists a wide range of brief cognitive assessments that have gained both scientific and clinical credibility, readily available to clinicians of all professions. The Mini-Mental State Examination[2] is pre-eminent in this field. It is easily administered and requires no training. The test consists of verbal and performance components. The verbal subtests evaluate orientation in time, memory and attention. The performance subtests involve the naming of objects, execution of written and spoken orders, writing, and copying a complex polygon. It takes a relatively short time to administer, and can be carried out by medical and paramedical staff. It has been extensively validated and has high inter-rater and test–retest reliability. Culture and social status significantly affect the scores[3] but it has been employed in the context of transcultural epidemiological studies in which modifications have been made[4]. The Standardized Mini-Mental State Examination is a derivative designed to promote standardization and inter-rater reliability[5].

The Blessed Dementia Rating Scale[6] has been a source scale for the development of further rating instruments. Cognitive assessment includes memory and information items. The second part consists of items of behaviour. The scale has been validated through correlation with mean brain cortical plaque counts. It "ceilinged" with the correlation declining sharply in clinically severe dementia sufferers. The 10 most useful questions differentiating between normal and abnormal cognitive functioning have been extracted[7] and are used as the Abbreviated Mental Test Score, giving comparable results to the full Blessed scale. The latter has been used in a simple test of mental impairment in functionally and mildly organically ill patients attending a day hospital[8] and has been used in screening for organic disorder and predicting change over a 2-year period[9]. The study evaluated the degree of disability and was used in the planning of social support.

The Clifton Assessment Procedures for the Elderly (CAPE) consists of two sub-scales, the Cognitive Assessment Scale and the Behaviour Rating Scale, derived from the Stockton Geriatric Rating Scale, designed to be used by nurses[10]. It was devised as a brief measure of psychological functioning for chronic psychiatric patient groups and has been validated against the outcome of day hospital and day centre care[13]. There is poor inter-rater reliability of the Gibson Maze component, which has to be completed by the patient. Despite these problems, the CAPE provides a well-validated, useful instrument that does not take too long to complete. Other common instruments include the Mental Status Questionnaire[14] (MSQ), requiring some training, as questions are asked in a standardized fashion. The Short Orientation–Memory–Concentration Test was developed from the MSQ and consists of six items concerning orientation and memory[15]. One of the more recent developments has been the Clock Drawing Test, which assesses frontal and temporoparietal functions, providing a useful bedside assessment[16].

SCALES FOR RATING BEHAVIOUR AND SELF-CARE

The Stockton Rating Scale (from which items of the CAPE were derived) is pre-dated by the Crichton Behavioural Rating Scale (CBRS)[17]. The CBRS rates 10 aspects of behaviour, including the functions of orientation, communication and mood. The addition of a memory item allows the generation of a "confusion" score that is sensitive to change in mentally ill patients. A modified version has been used in the context of nursing home residents.

The Performance Test for Activities of Daily Living (PADL)[18] was developed for the US/UK Cross-National Project. It assesses the degree of autonomy of elderly psychiatric subjects in activities of daily living. It is presented as a test of praxis containing 16 subtests. Lawton and Brodie developed the Instrumental Activities of Daily Living Scale (IADL) and the Physical Self-maintenance Scale[19]. The IADL is widely used to evaluate the degree of

physical and instrumental autonomy of elderly subjects. It takes 5 min to deliver and has been used as a base instrument for more recent developments in this field. Both the IADL and the PADL are task-based scales using simple scoring systems.

The Stockton and other scales[20] inspired the Physical and Mental Impairment of Function Evaluation in the Elderly (PAMIE). The assessment is completed with the aid of simply formulated items not requiring rater interpretation. It measures behavioural characteristics in patients suffering from chronic diseases, with particular reference to the elderly. Two other scales, the Psychogeriatric Dependency Rating Scale (PGDRS)[21] and the Geriatric Behavioural Scale[22], have been developed by nurses, psychologists and psychiatrists. Both scales have been used for the assessment of dementia and physical incapacity. They have been well validated in the context of prognostic ability over a period of 1–2 years. The only scale designed to examine behaviour in elderly schizophrenic subjects is the Nurses' Observation Scale for Inpatient Evaluation (NOSIE)[23]. The scale consists of 30 items and takes about 20 min to complete. It is based on 3-day consecutive observation of the patient and has a frequency scale of 0–4 for each item.

A number of scales designed to be completed by nurses and carers address disruptive, antisocial and aggressive behaviour in dementia sufferers. These include the Overt Aggression Scale[24], The Disruptive Behaviour Rating Scale[25], The Nursing Home Behaviour Problem Scale[26] and the Brief Agitation Rating Scale[27]. The Caretaker Obstreperous-Behaviour Rating Assessment (COBRA)[28] and the Ryden Aggression Scale[29] are slightly longer, taking up to 30 min to complete.

SCALES ASSESSING CARERS AND ENVIRONMENT

The Multiphasic Environment Assessment Procedure[30] is a relatively well-validated questionnaire for the assessment of the environment in which dementia sufferers are nursed. It enables the assessment of the complex relationships existing between physical environment, the policies and the characteristics of the staff and residents. Adaptations have to be made for its use in the UK, as it was designed and validated in North America[31]. The Social Network Assessment Scale[32] has been used in typing social networks of older dementia sufferers.

SCALES ASSESSING CARERS

Gilleard[33] developed the Problem Checklist and Strain Scale, designed to assess problems experienced by carers. Other less well-known instruments include those designed to assess psychological problems facing the carer: the Ways of Coping Check List[34] and the Burden Interview[35]. The Relatives' Stress Scale[36] enables the relatives to make a standard assessment of stress they are experiencing as a result of having to care for an elderly demented person living at home. The Caregiver Activity Survey[37] quantifies the time a caregiver devotes to the patient, and the Marital Intimacy Scale[38] specifically examines the psychological and emotional consequences of caring for an ill spouse.

RATING SCALES FOR MORALE AND MOOD

The Measurement of Morale in the Elderly Scale consists of items extracted from empirical observations[39]. It is a long, structured interview lasting 2–4 h. A degree of training and knowledge of the instrument is required before it is used, in order to achieve satisfactory levels of reliability. A shorter morale scale, The Philadelphia Geriatric Centre Morale Scale[40], takes 10 min and requires no training. The questions are of a forced-choice type and are read to the respondent. There is an internal consistency of factors and the scale has had fairly wide use. It is a multi-dimensional instrument for use in the very old and was particularly designed not to provoke fatigue or excessive inattention.

Depression rating scales should only be employed in rating depression in older people if validation studies have been reported. Some rating scales have been specifically designed for this age group, accommodating the issues of concomitant physical illness and cognitive change. The Self Care (D)[41] is a self-administered scale. It has been used in the community for the screening and rating of severity of depression in the elderly. It was found to be a sensitive indicator of depression. It may have potential use in the monitoring of change as a consequence of antidepressant medication. The scale has been validated in a pilot study in elderly, continuing-care patients[42]. The Geriatric Depression Scale (GDS)[43] was devised by compiling 100 questions used by professionals in the diagnosis of depression. O'Riordan *et al.*[44] recently used the scale in a large survey of patients admitted to an acute medical geriatric assessment unit, where there was a high prevalence of physical illness and cognitive impairment. They found that the GDS appeared to be a sensitive test for depression in this group, but was sufficiently non-specific to require psychiatric evaluation of patients with high scores to establish the accurate prevalence of depressive illness. The instrument exists in 15-item[45], 10-item and four-item versions[46]. Other scales that are used by clinicians include the Cornell Scale for depression in dementia[47], the Brief Assessment Schedule Depression Cards[48] and the ELDRS[49] designed to be used with an informant as well as the patient. The Centre for Epidemiological Studies Depression Scale (CES-D)[50] is a self-rating scale that has been found to be of value in screening community samples.

CONCLUDING REMARKS

This chapter does not provide a comprehensive account of the wide variety of instruments that are available for the assessment of the elderly mentally ill. Attention has been given to those instruments that have been relatively well validated, with evidence of reliability, that are easy to use with little or no training. They have been loosely categorized by function and use. Care must be taken in their application, with appropriate supervision and standardization in view of frequent problems of inter-rater reliability. In isolation, these instruments are of limited clinical value, but in the context of a multi-professional team they do have important potential in screening, clinical audit, examining issues of service need and rating change.

Comprehensive Interviews

OARS Methodology

Gerda G. Fillenbaum
Duke University Medical Center, Durham, NC, USA

The OARS (Older Americans Resources and Services) methodology was developed over two decades ago in response to a request "to assess alternative strategies to institutionalizing frail older adults"[1]. To address this issue, a three-element model was developed, which allows one to: (a) assess adults at all levels of functioning from excellent to totally impaired, using a multidimensional perspective; (b) determine the extent of use of and perceived need for each of 24 broadly encompassing but non-overlapping generically-defined services, which can be aggregated into costable packages; and consequently (c) to examine the impact of the identified service packages on persons defined in terms of their multidimensional functional profiles.

The questionnaire developed to operationalize the first two elements of the model is not restricted to it, but has enjoyed more varied use. The questionnaire is in two parts (*see* summary in Table 1). Part A assesses the level of functioning in five areas. Three areas reflect personal functioning—mental health, physical health, and activities of daily living; two reflect environmental conditions—social resources and economic resources. In each area the information obtained (from the subject or an informant) can be summarized on a six-point scale, ranging from excellent to totally impaired functioning. Review across all five areas provides a profile, making it possible to identify where functional strengths and weaknesses lie. Each area is itself multidimensional, so allowing users to examine specific aspects of particular areas of functioning and permitting more accurate identification of service impact.

Part B focuses on services assessment. To ensure accurate identification, each service is defined in terms of its purpose, the activity involved, the personnel who may provide the service, and the units in which it is to be measured (to facilitate costing). So, a resident of a nursing home would not be rated as receiving "nursing home services", rather, the precise services received there (e.g. nursing care, meal preparation, occupational therapy), the amount, and the type of provider (formal or informal) would be recorded. Need for services is self-assessed.

On average, the OARS questionnaire takes 40 min to administer (training in this is provided). Validity and reliability have been determined. It is available, and has been validated, in a number of languages. The questionnaire has been used for purposes as varied as teaching, clinical and population assessment, agency evaluation, staffing determination, service impact, prediction of service needs, determination of preferred service aggregation, and estimating service cost in different settings. An archive of OARS-based data sets is maintained at the Duke Aging Center.

Table 1. Overview of OARS multidimensional functional assessment questionnaire

Part A, Assessment of functional status	Part B, Services assessment
Demographic	Transportation
	Social/recreational services
Social resources	Employment services
Interaction	Sheltered employment
Affect	Educational services, employment-related
Extent of availability of help	Remedial training
Economic resources	Mental health services
Occupation	Psychotropic drugs
Income (by source)	Personal care services
Housing	Nursing care
Self-assessed adequacy of income	Medical services
	Supportive devices and prostheses
Mental health	Physical therapy
Short Portable Mental Status Questionnaire (to assess level of cognitive functioning)	Continuous supervision
	Checking services
Short Psychiatric Evaluation Schedule (to assess presence of psychiatric problems)	Relocation and placement services
	Homemaker–household services
Self-assessed mental health	Meal preparation
Physical health	Administrative, legal and protective services
Prescribed medications	Systematic multidimensional evaluation
Current illnesses and conditions and their impact	Financial assistance
Alcohol use	Food, groceries
Level of activity	Living quarters (housing)
Self-assessed physical health	Coordination, information and referral services
Activities of daily living (ADL)	
Instrumental ADL	
Physical ADL

The Comprehensive Assessment and Referral Evaluation (CARE): An Approach to Evaluating Potential for Achieving Quality of Life

Barry Gurland and Sidney Katz
Columbia University Stroud Center, New York, USA

PURPOSES

The CARE covers a wide range of indicators of a person's potential for achieving a preferred quality of life. Its bounded focus is on health and social problems associated with aging, including psychiatric disorders. Originally developed for intensive studies of community-dwelling elders[1], the rater-administered CARE has given rise to versions that have been made briefer by concentrating on key scales (the CORE-CARE[2] and the SHORT-CARE)[3], suitable for residents of institutions (the IN-CARE)[4], clinically focused (the CLIN-CARE)[5], and capable of self-administration (the SELF-CARE). There is also an INFORMANT version[6] of the CARE.

THEORETICAL BASE[7]

The phrase ''quality of life'' is invoked to direct attention to processes of striving to achieve or preserve a preferred manner of living. The processes involve strategies that allow relevant choices to be made and implemented. The strategies can be impeded by certain health and social problems that may occasion help-seeking contacts with informal or formal care-givers or services. The CARE seeks to assess the person's ability to deal with the strategies necessary for choosing and attaining a preferred manner of living. It does not attempt to define the latter. Information on processes can come from many sources, touching on many aspects of living, reaching beyond the person's immediate status into the present and historical context, modified by expectations of the future, and qualified by personal and cultural preferences. It is recognized that the gathering of such information is very constrained by its complexity, openness to change and inherent uncertainties, as well as by the necessary rigidities of the systematic assessment procedures.

STYLE

The general style of the CARE relies on scripted questions with pre-coded answers. The questioning is tactful and with an organization that is understandable to the interviewee, Header questions allow sections to be skipped if unlikely to be productive. Computer-assisted programs guide interview administration, so as to avoid missed or conflicting ratings. Information can be analyzed at the level of discrete items, global ratings, scales, hierarchically-arranged classes of severity, and threshold scores relating to diagnosis and need for investigation and possible treatment.

DOMAINS

Each domain targets the capacity to meet a distinctive challenge to achieving a preferred quality of life. Nineteen quality of life domains[8] have been identified and matched to items in the CARE: moving purposefully (mobility); maintaining self routinely (basic activities of daily living); using the immediate environment (instrumental activities of daily living); manipulating household appliances (technological activities of daily living); finding one's way around (navigational orientation); keeping track of time and space (continuity orientation); gathering information (receptive communication); expressing needs (expressive communication); preserving health (health and safety practices); protecting physical and mental comfort (emotional and physical status); engaging in social relations; exercising choice; managing material resources; finding the best environment; obtaining meaningful gratifications; recognizing one's own state of health (self-perceived health); taking account of the future (pessimism, optimism. realism); balancing competing qualities of life; setting and achieving goals. The domain content and labels are keyed to adaptive behaviors in pursuit of quality of life (more conventional captions are shown in parentheses).

SUBJECTIVITY AND OBJECTIVITY

The CARE does not beg the issue of whether quality of life is primarily subjective or objective, preferring to regard both as important strategies in the pursuit of quality of life. Subjective (e.g. feelings, attitudes), quasi-objective (self-reports of objective status) and mainly objective (tests and observations) aspects of quality of life are represented, thus allowing their interrelationships and their respective effects and outcomes to be examined. For example, questions on activities of daily living probe self-reported task performance, views on the extent to which health limits desired activities, informant views on the elder's functioning, tests of range of movement and observations on mobility. A supplement tests a simulation of various basic and instrumental tasks (the Performance of Activities of Daily Living, or PADL)[2]. Similarly, inquiries on cognitive status range from self-reported difficulties with memory to formal tests of memory and orientation, and a supplement (the Medication Management Test, or MMT)[10,11] tests higher-order cognitively-driven performance.

SEVERITY LEVELS

Threats to quality of life are graded in terms of the degree to which they overshadow living at a critical point in time (intensity) and over time, experiences, and situations (extensity). This approach has been more completely modeled within the CARE domain of emotional comfort, as expressed in the seven levels of the index of affective suffering (IAS)[12,13]. Each level is operationalized by symptom criteria that convey the severity meanings of suffering in a way not equaled by symptom scores or diagnosis. This model of severity is also worked out for the CARE domains dealing with functioning in the activities of daily living. Current development is concerned with deriving a measure

of the continuities underlying the progression of functional decline.

MECHANISMS

Threats to quality of life, such as those measured by the CARE, may arise from health and social conditions; the presence of the latter can be suggested by certain syndromes. The CARE items include syndromes of cardiac failure or angina, arthritic pain, respiratory problems, effort intolerance, cognitive deficits, Parkinson's disease, stroke, perceptual deficits, vertigo, falls, experience of crime, and social isolation and desolation. Conversely, there are characteristics of the threatened qualities of life that suggest certain mechanisms: one scale of functioning in the CARE is composed of higher-order tasks that are principally affected by cognitive mechanisms; similarly, certain somatic items are phrased to suggest a mood disorder and others to suggest a physical disorder. More directly, there are items to record what the individual blames as the cause of his/her threatened quality of life.

BIOMETRICS

Satisfactory reliability, validity and operational characteristics for discriminating diagnoses of the CARE scales have been established[14–18]. Transition tables show a range of incidence, chronicity and recovery from threats to quality of life[19]; these also reflect a power to predict specific quality-of-life outcomes. Cross-tabulations reveal that the various domains are sufficiently independent to be usefully measured separately but that there is substantial interaction between them.[20,21]

CULTURE-FAIR INDICATORS

Ethno-racial and educational variation in qualities of life have been found with CARE indicators[22,23], as with comparable instruments[24]. In order to minimize the confound of bias entering into such comparisons, item response theory has been applied to construct culture-fair CARE scales of mood, cognition and functioning in the activities of daily living[25].

MODULAR USES

Although the full CARE is more than the sum of its parts, the scales can be, and have been, used alone and in various combinations. This has enabled the assembly of its different versions.

WHOLE-PERSON VIEW[26]

Profiles of CARE indicator severity scales are generated by computer algorithms, giving an overview of the person's strengths and vulnerabilities for preserving and improving quality of life. Global concepts are also embodied in items on self-perceived general health and in visual analog scales on physical and psychological distress and task and social functioning: a supplementary single-page rapidly completed set of visual analog scales (the QoL-100) has proved useful for a snap-shot of the quality of life potentials of seriously ill patients or where frequent follow-up assessments are needed. Psychiatric diagnoses have been generated using a computerized decision tree[27,28].

APPLICATIONS

Taken together with its versions and supplements, the CARE has been applied to epidemiological[29] surveys[30–33], public health policy[34–39] and clinical management in primary medical care[40], home care[41] and occupational therapy. A Training Manual is available.

FURTHER DEVELOPMENT

The Stroud Center's program is designed to contribute to understanding the nature of the parts and the connected whole of a person's quality of life. Experience with applications, modifications and analyses of the CARE is leading to new and better ways of assessing quality of life.

Delirium—An Overview

Andrew F. Fairbairn

Centre for Health Care of the Elderly, Newcastle upon Tyne, UK

Delirium is a state of acute confusion due to an underlying physical cause. Associated with the disorder of cognition and attention, there is frequently disturbed psychomotor behaviour and disturbance to the sleep–wake cycle. It is a common feature in those, particularly older patients, who present as acute medical emergencies. As a common, potentially highly treatable condition, it is associated with major health care costs. It is also under-recognized and associated with longer periods of inpatient stay. It is a recognized mental disorder under the English Mental Health Act, which has significance in relation to compulsory treatment.

Formal diagnostic criteria for delirium were only first introduced in DSM-III. These criteria were further revised for DSM-IV and the criteria for general medical conditions are shown in Table 35.1. DSM-IV critera are also described as more specific for delirium in relation to substance abuse. The main changes in the criteria are a general simplification with less emphasis on deficits of attention and more emphasis on the syndrome developing over a short period of time.

Confusion, or cognitive impairment, commonly only occurs in three conditions, namely delirium, dementia and depression. Two of the "3Ds" are eminently treatable, therefore it is to be regretted that cognitive impairment is primarily associated with dementia and hence only belatedly recognized as a potentially treatable condition in the case of this particular chapter's subject, delirium.

The rest of the chapter will discuss incidence and risk factors. There is an expanded section on clinical features and discussion of assessment scales, neuropathogenesis, appropriate investigations and treatment.

INCIDENCE

Delirium occurs in 14–56% of older hospitalized patients[1]. It is lower after elective surgery and higher in acute medical admissions. Patients who have suffered delirium during a hospital admission tend to stay in hospital for longer and have greater requirements for rehabilitation and require increased home care services[2].

RISK FACTORS

Inouye *et al.*[1] propose a multifactorial model for delirium, including predisposing factors and precipitating factors. The study identifies four predisposing factors for delirium, visual impairment, severe physical illness, cognitive impairment and blood urea nitrogen (BUN):creatinine ratio i.e. an indicator of dehydration. Using complex methodology, they identified a hierarchy of precipitating factors, the most significant of which were major surgery, stay in intensive care, multiple medication and sleep deprivation. Their conclusion was that the aetiology of delirium is multifactorial, but that certain predisposing factors, combined with a weighting of precipitating factors can make the likelihood of delirium much more predictable. Elie *et al.*[3] similarly identified risk factors that included dementia, advanced age and medical illness. Robertsson *et al.*[4] looked at the likelihood that a pre-existing dementia could predispose to the onset of delirium and showed that late-onset Alzheimer's disease was more likely to do so than early-onset Alzheimer's disease and that vascular dementia was more likely to do so than early-onset Alzheimer's disease.

CLINICAL FEATURES

Whilst DSM-IV attempts to define the clinical features, it is worth remembering that Lipowski[5] has regularly warned about the subtle "prodromal, non-specific" features that can even precede the more formal syndrome. This can be as simple as increased anxiety or subtle levels of agitation. The cardinal feature is probably a relatively sudden change in cognition but there can also be perceptual disturbances. Patients can latterly describe great difficulties in differentiating between reality and hallucination. Visual hallucinations are classically more common than auditory hallucinations and are generally unpleasant and frightening. Thinking is disorganized, slowed and impoverished. Memory is impaired across the entire spectrum of registration, retention and recall. Short-term memory may well be impaired, secondary to poor attention, and patients may be inclined to confabulate.

The impact of delirium on psychomotor behaviour is variable. Some delirious patients will become agitated, restless and hypervigilant. In contrast, some patients will become withdrawn, with slowed physical responses. Finally, the picture of psychomotor activity can be mixed with oscillation between hyper- and hypo-activity.

Having described the classic clinical features above, it should be remembered that Treloar and McDonald[6] have placed emphasis on the "quiet syndrome". They argue that one of the reasons that delirium is under-recognized is because of the frequency of the hypo-active type of syndrome. There is evidence that nurses are better than doctors at identifying the syndrome of delirium and there is tentative evidence that different aetiologies may possibly account for differentiation in the clinical picture. Zou *et al.*[7] showed that diagnosis by a nurse clinician using a standardized rating scale (the Confusion Assessment method) and multiple

Table 35.1 Diagnostic criteria for 293.0 Delirium, due to . . . (indicate the general medical condition)

A.	Disturbance of consciousness (i.e. reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention
B.	A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre-existing, established or evolving dementia
C.	The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day
D.	There is evidence from the history, physical examination or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition

Coding note: If delirium is superimposed on a pre-existing Dementia of the Alzheimer's Type or Vascular Dementia, indicate the delirium by coding the appropriate subtype of the dementia, e.g. 290.3 Dementia of the Alzheimer's Type, with Late Onset, with Delirium.
Coding note: Include the name of the general medical condition on Axis I, e.g. 293.0 Delirium Due to Hepatic Encephalopathy; also code the general medical condition on Axis III (see Appendix G for codes)

observation points was better than a one-off assessment by a psychiatrist. This study reinforces the importance of repeated observations and the value of a structured approach to the diagnosis.

ASSESSMENT SCALES

Because of the problem clinicians have in recognizing delirium, there have been a number of attempts to create assessment scales to assist in diagnosis. In the development of these scales, one of the major problems has been that cognitive impairment is, of course, a common symptom but that it is not specific to delirium. A number of instruments to evaluate delirium have been developed, mainly using DSM-III-R criteria. Many of them are multi-item scales, which probably have limited value in the clinical setting, but one, the Confusion Assessment Method (CAM), is intended to be used by physicians and has two versions with only nine and four items, respectively. Non-specific cognitive tests, such as the well known Folstein Mini-Mental State Examination, cannot specifically address the differentiation between delirium and dementia. However, it would seem that the introduction of appropriately clinically friendly scales for delirium, used by skilled nurse clinicians, might well increase the recognition of delirium in acute medical settings[7].

NEUROPATHOGENESIS

Whilst delirium is regarded as a syndrome with global dysfunction of cognition, attempts have been made to address whether there are disorders of specific brain pathways that can account for specific symptomatology, the analogy being that certain specific strokes can be associated with syndromes, for example, left frontal strokes being associated with depression. Trzepacz[8] has reviewed a number of brain scan studies which, although they are limited to studies with only a small series or even single case reports, tend to show that frontal cortex, anteromedial thalamus, right basal ganglia, right posterior parietal cortex and medial basal temporal and occipital cortex may be areas particularly associated with delirium.

The neurochemistry of delirium is believed to mainly involve under-activity of the cholinergic system. That said, on the basis that most neurochemical systems in the brain are in dynamic relationships with others, it is highly likely that this acetylcholine hypothesis also relates to a balance with the dopamine system. It can be speculated that, in the future, there may be scope to manipulate the balance of the acetylcholine and dopamine systems in such a way as to treat the symptoms of delirium, very possibly with the new cholinesterase inhibitors.

INVESTIGATIONS

Delirium, particularly in the elderly, tends to have a multifactorial aetiology. As it can be due to almost any underlying physical problems, the old adage that "common things occur commonly" must be relevant when investigating the causes. These are likely to be infections, cardiac problems, iatrogenic medication, dehydration, stroke disease, diabetes and cancer. Naughton *et al.*[9] reported a study of head CT scans in delirium. 15% were positive for an acute condition (haemorrhage, haematoma, space-occupying lesion or infarct) and 95% of these positive scans were found in patients with impaired consciousness or a new focal neurological finding detected during the episode of delirium. Their main conclusion was that there was considerable variation in brain CT scanning of older people with delirium.

TREATMENT

First, the aetiological factors must be identified and treated or corrected if at all possible. Whilst these are being identified, symptomatic and supportive therapies will be required. Over the years, Lipowski[5] in particular has recommended an appropriate environment for managing patients with delirium. He has described a well-lit room with familiar items and clearly visible clock and calendar. Inouye *et al.*[10] have systematically studied this in a paper describing a multi-component intervention to prevent delirium in hospitalized older patients. Their risk factors and intervention protocols are detailed in Table 35.2. The study provides important evidence that a multicomponent, targeted intervention to prevent delirium in hospitalized older patients can work, particularly targeting those at high risk from previously identified precipitating and predisposing factors. Wahlund and Björlin[11] report on a specialized delirium ward and argue that such a specific ward is best placed to clinically manage, investigate and treat patients with delirium. Despite the importance of primary prevention and the probable value of special delirium wards, there may be a need for antipsychotic medication. Haloperidol probably remains the antipsychotic of choice[12], although little is currently known about the efficacy of the new atypical antipsychotics in delirium. Benzodiazepines probably remain the preferred medical treatment in delirium due to alcohol.

As noted above, delirium *per se* makes a longer hospital stay likely, with consequent increased health care costs. That said, the mean duration of delirium is shorter in post-operative patients compared to acute medical patients[13]. The long-term prognosis of delirium used to be felt to be simply that of the underlying condition. However, a recent publication[14] flags up the possibility that the long-term prognosis after delirium is poor and, indeed, delirium might be a marker for decline. Also in contrast to traditional views, there is now a view that delirium is not always entirely reversible.

Table 35.2 Risk factors for delirium and intervention protocols

Targeted risk factor and eligible patients	Standardized intervention protocols	Targeted outcome for reassessment
Cognitive impairment*		
All patients, protocol once daily; patients with base-line MMSE score of 520 or orientation score of 58, protocol three times daily	Orientation protocol: board with names of care-team members and day's schedule; communication to reorientate to surroundings Therapeutic activities protocol: cognitively stimulating activities three times daily (e.g. discussion or current events, structured reminiscence or word games)	Change in orientation score
Sleep deprivation		
All patients; need for protocol assessed once daily	Non-pharmacologic sleep protocol: at bedtime, warm drink (milk or herbal tea), relaxation tapes or music, and back massage Sleep enhancement protocol: unit-wide noise reduction strategies (e.g. silent pill crushers, vibrating beepers and quiet hallways) and schedule adjustments to allow sleep (e.g. rescheduling of medications and procedures)	Change in rate of use of sedative drug for sleep[{]
Immobility		
All patients; ambulation whenever possible, and range-of-motion exercises when patients chronically non-ambulatory, bed- or wheelchair-bound, immobilized (e.g. because of extremity fracture or deep venous thrombosis), or when prescribed bed rest	Early mobilization protocol: ambulation or active range of motion exercises three times daily; minimal use of immobilizing equipment (e.g. bladder catheters or physical restraints)	Change in Activities of Daily Living score
Visual impairment		
Patients with 520/70 visual acuity on binocular near-vision testing	Vision protocol: visual aids (e.g. glasses or magnifying lenses) and adaptive equipment (e.g. large illuminated telephone keypads, large-print books and fluorescent tape on call bell), with daily reinforcement of their use	Early correction of vision, 448 hours after admission
Hearing impairment		
Patients hearing 46 of 12 whispers on Whisper Test	Hearing protocol: portable amplifying devices, earwax disimpaction, and special communication techniques, with daily reinforcement of these adaptations	Change in Whisper Test score
Dehydration		
Patients with BUN:creatinine ratio 418, screened for protocol by geriatric nurse-specialist	Dehydration protocol: early recognition of dehydration and volume repletion (i.e. encouragement of oral intake of fluids)	Change in BUN:creatinine ratio

*The orientation score consisted of results on the first 10 items on the Mini-Mental State Examination (MMSE).
[{] Sedative drugs included standard hypnotic agents, benzodiazepine and antihistamines, used as needed for sleep.

Finally, delirium is a mental disorder and as such comes under the English Mental Health Act. Very occasionally, therefore, it may be legitimate to use the Mental Health Act to facilitate the treatment of delirium.

SUMMARY

Delirium remains a common, under-diagnosed symptom of underlying physical illness in older people. This alone makes it an important health economic issue. Primary prevention of delirium is now of proved efficacy and, generally, the prognosis of delirium is that of the underlying physical disorder.

Delirium in Institutions

Barbara Kamholz and Christopher Colenda
Michigan State University, East Lansing, MI, USA

The prevalence of delirium is approximately 10–40% of patients on acute medical and surgical units. The incidence for newly admitted patients ranges from 25% to 60%[1]. Delirium is commonly misdiagnosed as depression; up to 41.8% of inpatient psychiatry consultations for depression actually result in a diagnosis of delirium[2,3]. Delirium has a number of adverse outcomes, and may itself be looked upon as a ''symptom'' of problems in the delivery of hospital services[8]. It is the single most important factor contributing to in-hospital complications, such as falls and pressure sores[4]. It has a significant impact on increasing hospital length of stay[4,5] and upon the need for discharge to long-term care institutions[6]. It is the single strongest predictor of impaired daily function (AFL) at 6 months[7], although most studies have found surprising little impact on mortality[4,7]. Delirium may not be as reversible as previously thought; Levkoff found that only 17.6% of all new symptoms of delirium had cleared fully at 6 month follow-up[5]. Delirium is the most frequent complication of hospitalization in older patients.

DIAGNOSIS

Careful diagnosis of delirium is essential, as up to 66% of cases are missed[1]. Delirium can be systematically diagnosed using the Folstein Mini-Mental State Examination (MMSE)[9] in combination with the Confusion Assessment Method[1], with the optimal technique using several observation points[10]. Inattention is a critical criterion of delirium and is essential in differentiating it from depression and dementia. A recent model developed by Inouye and colleagues[1] at the Yale University Elder Life Program demonstrates that the probability of developing delirium is somewhat predictable among a population of vulnerable patients characterized by older age, high medical co-morbidity, sensory (visual/hearing) impairment and baseline cognitive impairment. Among this vulnerable group, the introduction of specific precipitating causes of delirium (such as indwelling catheter, use of restraints, and new medical complications) has been shown to increase the probability of delirium in proportion to the number of precipitating factors present.

TREATMENT

As yet, despite promising evidence that neuroleptics may improve the course of delirium itself[11] and that cholinesterase inhibitors may be effective[12], there are as yet no specific recommended pharmacological treatments for delirium. However, there is more hopeful evidence that delirium may be prevented. An intervention based on Inouye's approach provides: sensory correction aids (e.g. glasses and hearing aids); reorientation; therapeutic cognitive activities; a non-pharmacological sleep protocol; a dehydration protocol; and an early-mobilization protocol. This resulted in a significant reduction in new cases of delirium among patients at intermediate baseline risk for delirium. It is notable that this strategy had no impact on ''delirium in progress'; its primary clinical impact lay in prevention[13]. Further work on interventions for delirium will clearly be of vital importance to the reduction of the risks for delirium in institutions and for its treatment. The costs incurred by early detection may well be more than offset by savings in decreased length of stay, decreased rates of institutionalization and decreased rates of in-hospital complications[8].

Delirium in Institutions

Barbara Kamholz and Christopher Colenda
Michigan State University, East Lansing, MI, USA

The prevalence of delirium is approximately 10–40% of patients on acute medical and surgical units. The incidence for newly admitted patients ranges from 25% to 60%[1]. Delirium is commonly misdiagnosed as depression; up to 41.8% of inpatient psychiatry consultations for depression actually result in a diagnosis of delirium[2,3]. Delirium has a number of adverse outcomes, and may itself be looked upon as a "symptom" of problems in the delivery of hospital services[8]. It is the single most important factor contributing to in-hospital complications, such as falls and pressure sores[4]. It has a significant impact on increasing hospital length of stay[4,5] and upon the need for discharge to long-term care institutions[6]. It is the single strongest predictor of impaired daily function (AFL) at 6 months[7], although most studies have found surprising little impact on mortality[4,7]. Delirium may not be as reversible as previously thought; Levkoff found that only 17.6% of all new symptoms of delirium had cleared fully at 6 month follow-up[5]. Delirium is the most frequent complication of hospitalization in older patients.

DIAGNOSIS

Careful diagnosis of delirium is essential, as up to 66% of cases are missed[1]. Delirium can be systematically diagnosed using the Folstein Mini-Mental State Examination (MMSE)[9] in combination with the Confusion Assessment Method[1], with the optimal technique using several observation points[10]. Inattention is a critical criterion of delirium and is essential in differentiating it from depression and dementia. A recent model developed by Inouye and colleagues[1] at the Yale University Elder Life Program demonstrates that the probability of developing delirium is somewhat predictable among a population of vulnerable patients characterized by older age, high medical co-morbidity, sensory (visual/hearing) impairment and baseline cognitive impairment. Among this vulnerable group, the introduction of specific precipitating causes of delirium (such as indwelling catheter, use of restraints, and new medical complications) has been shown to increase the probability of delirium in proportion to the number of precipitating factors present.

TREATMENT

As yet, despite promising evidence that neuroleptics may improve the course of delirium itself[11] and that cholinesterase inhibitors may be effective[12], there are as yet no specific recommended pharmacological treatments for delirium. However, there is more hopeful evidence that delirium may be prevented. An intervention based on Inouye's approach provides: sensory correction aids (e.g. glasses and hearing aids); reorientation; therapeutic cognitive activities; a non-pharmacological sleep protocol; a dehydration protocol; and an early-mobilization protocol. This resulted in a significant reduction in new cases of delirium among patients at intermediate baseline risk for delirium. It is notable that this strategy had no impact on "delirium in progress'; its primary clinical impact lay in prevention[13]. Further work on interventions for delirium will clearly be of vital importance to the reduction of the risks for delirium in institutions and for its treatment. The costs incurred by early detection may well be more than offset by savings in decreased length of stay, decreased rates of institutionalization and decreased rates of in-hospital complications[8].

Prognosis of Delirium

A. Treloar
Memorial Hospital, London, UK

Studies of outcome have started to challenge the assumption that delirium is a truly reversible disorder with a good prognosis. Prospective outcome studies of delirium are required to describe its prognosis. Using change in MMSE[1] score as the outcome measure, Fields *et al*.[2] found that by no means all patients improve, and some get worse. Treloar and Macdonald[3] found that although many acute patients had reversible cognitive dysfunction, few regained normal cognition. Some patients took the full 3 month time-course of the study to start their recoveries. Studies based upon standard diagnoses of delirium have also reported poor recovery at follow-up[4]. Kolbeinsson and Jonsson[5] found that elderly patients with DSM-III-R[6] delirium but not dementia at outset, had dementia at follow-up in 70% of cases. Cole *et al*.[7] found that less than 50% recovered mentally at follow-up. Rudberg *et al*.[8] showed delirium lasting over periods of several weeks (even though patients did not meet Delirium Rating Scale[9] criteria for delirium continuously). Cognitive deficits and behavioural abnormalities persisted in the majority of patients for at least 6 months[10] Kaponen *et al*.[11] found infrequent good cognitive outcome following delirium at one year.

Delirious patients stay longer in hospital than those without delirium. Diagnosis-related group length of stay of 13 days for patients with delirium compares with 3.3 days for those with dementia[12]. Physical morbidity may be exacerbated by psychiatric co-morbidity. Delirium is associated with death in up to 33%[13]. It is frequently asserted that mortality is purely the result of the physical illness, but this is a difficult hypothesis to test. It would be very surprising if the stupor, retardation and poor compliance with treatments seen in delirious patients did not contribute to mortality from physical illness. Patients with delirium after hip fracture surgery are at greater risk of incontinence, urinary tract infections and pressure sores[14]. Delirium in patients with hip fractures also predicts higher long-term mortality and poor functional recovery[14–16]. Francis and Kapoor[17] found that delirium predicted a doubling of mortality attributable to functional impairment, and in survivors predicted loss of ability to live independently. Levkoff *et al*.[10] found that new symptoms of delirium resolve at 6 months in only 17.7%.

The prognosis of delirium is almost certainly not, therefore, one of early full recovery. Rather, delirium is a condition with a slow recovery and one which often fails to resolve completely.

Nosology of Dementia

Ingmar Skoog[1] and John R. M. Copeland[2]

[1]*Institute of Clinical Neuroscience, University of Göteborg, Sweden, and*
[2]*Royal Liverpool University Hospital, Liverpool, UK*

In the early 1950s, Sir Martin Roth defined dementia as "severe decline in memory accompanied by disorientation for time and place". The modern criteria emphasize that dementia is a global decline of intellectual functions that affects more areas than just memory. However, memory impairment is mandatory for the diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders*, Version III—Revised (DSM-III-R) and IV (DSM-IV) (see Tables 36.1 and 36.2), issued by the American Psychiatric Association[1,2] and in the *International Classification of Disease—*Edition 10 criteria for research (ICD-10), issued by the World Health Organization[3] (see Table 36.3). In these criteria, dementia is a syndrome characterized by a decline in memory and other intellectual functions (e.g. orientation, visuospatial abilities, language, thinking, executive function, problem solving, apraxia, agnosia). It is often accompanied by changes in behaviour or personality (e.g. loss of initiative, emotional lability, irritability, apathy, coarsening of social behaviour, change in mood). These latter symptoms are mandatory for a diagnosis in ICD-10, diagnostic in the presence of memory dysfunction in DSM-III-R and not included in DSM-IV.

An interesting difference between DSM-III-R and DSM-IV is that DSM-III-R requires impairment in short *and* long-term memory, while DSM-IV states that the impairment should include impairment in either short *or* long-term memory. In DSM-IV, in contrast to DSM-III-R and ICD-10, the criteria for dementia are integrated with the criteria for different types of dementia (such as Alzheimer's disease and vascular dementia). It is thus not permitted to diagnose the dementia syndrome *per se*, but the subcriteria for dementia are identical for all types.

The symptoms of dementia are on a continuum with normal behaviour, which often makes it difficult to know where the line should be drawn between normal function and mild dementia. This dimensional rather than categorical character makes mild dementia difficult to separate from normal ageing[4]. Fairly small differences in criteria may have large effects on the prevalence rates. Mowry and Burvill[5] found a variation in the prevalence of mild dementia ranging from 3% to 64% when different criteria were used on the same population. Different criteria also diagnosed different individuals. If a decline from a previously higher level can be shown (by obtaining information from key informants or by following the patients over time), the validity may be higher[6]. The DSM-III-R, DSM-IV and ICD-10 use the degree of social consequences of the disorder ["sufficient to interfere with everyday activities" (ICD-10) and "significant impairment in social or occupational functioning representing a significant decline from a previous level of functioning" (DSM-IV)] as the criterion for demarcating normal from abnormal behaviour.

The modern concept of dementia does not imply anything about prognosis, i.e. the course may be progressive, static, fluctuating or even reversible.

DIFFERENT TYPES OF DEMENTIA

A dementia syndrome may be caused by more than 70 diseases, the most common being Alzheimer's disease and vascular dementias.

Alzheimer's Disease

The neuropathology of Alzheimer's disease (AD) is characterized by a marked degeneration of the neurons and their synapses and the presence of extensive amounts of extracellular senile plaques and intracellular neurofibrillary tangles in certain areas of the brain. The typical insidious onset and gradually progressive course is emphasized in the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS–ADRDA) criteria (Table 36.4), in DSM-III-R and in DSM-IV but not in ICD-10. Memory disturbance is the most prominent early symptom, but slight impairment of visuospatial functioning, language and concentration may occur. In the later stages, the symptomatology is more widespread. The NINCDS–ADRDA criteria, DSM-III-R, DSM-IV and ICD-10 require that the diagnosis of AD should be made in the absence of diseases that, in and of themselves, could account for the progressive deficits in memory and cognition. Possible AD, according to the NINCDS–ADRDA criteria, may be diagnosed in the presence of other diseases if they are not judged to have caused the dementia.

Alzheimer's disease is categorized into an early- and a late-onset form in DSM-IV and ICD-10, based on whether onset occurred before or after age 65 years. ICD-10 also specifies that the early-onset type should have a relatively rapid onset and progression or aphasia, agraphia, alexia, acalculia or apraxia, while the late-onset type should have a very slow, gradual onset and progression or predominance of memory impairment. Another subdivision is between familial AD (FAD) and sporadic AD. FAD has an autosomal dominant inheritance. Almost all cases with FAD have an early onset, while most cases of sporadic AD occur late in life. Familial clustering may occur also in sporadic AD[8].

Table 36.1 Dementia (DSM-IV) (adapted)

A1	Memory impairment (impaired ability to learn new information *or* to recall previously learned information) *and*
A2	One (or more) of the following cognitive disturbances: (a) Aphasia (b) Apraxia (c) Agnosia (d) Disturbance in executive functioning
B	The cognitive deficit in A1 and A2 *each* cause significant impairment in social *or* occupational functioning *and* represent a significant decline from a previous level of functioning

American Psychiatric Association[2].

Table 36.2 Dementia (DSM-III-R) (adapted)

A	Demonstrable evidence of impairment in short *and* long-term memory *and*
B	At least one of the following: (i) Impairment in abstract thinking (ii) Impaired judgement (iii) Other disturbances of higher cortical function, such as: aphasia, apraxia, agnosia, constructional difficulty (iv) Personality change
C	The disturbance in A + B significantly interferes with work *or* usual social activities *or* relationships with others
D	Not occurring exclusively during the course of delirium
E	Either (1) there is evidence from the history, physical examination, or laboratory tests of a specific organic factor (or factors) judged to be etiologically related to the disturbance, or (2) in the absence of such evidence, an etiologic organic factor can be presumed if the disturbance cannot be accounted for by any non-organic mental disorder

American Psychiatric Association[1].

Table 36.3 ICD-10 Criteria for dementia. Definition of dementia in the ICD-10 (adapted)

G1	There is evidence of each of the following:
(1)	A decline in memory (at least) sufficient to interfere with everyday activities, though not so severe as to be incompatible with independent living
(2)	A decline in other cognitive abilities characterized by deterioration in judgement and thinking, such as planning and organizing, and in the general processing of information (at least) sufficient to cause impaired performance in daily living, but not to a degree that makes the individual dependent on others
G2	Awareness of the environment (i.e. absence of clouding of consciousness)
G3	There is a decline in emotional control or motivation, or a change in social behaviour manifest as at least one of emotional lability, irritability, apathy or coarsening of social behaviour
G4	The symptoms in criterion G1 should have been present for at least 6 months

World Health Organization[3].

Table 36.4 NINCDS–ADRDA Criteria for Alzheimer's disease

1. Probable Alzheimer's disease:
   - Dementia
   - Deficits in two or more areas of cognition
   - Progressive worsening of memory and other cognitive functions
   - No disturbance of consciousness
   - Onset between ages 40 and 90
   - Absence of systemic disorders or other diseases that in and of themselves could account for the progressive deficits in memory and cognition

2. Possible Alzheimer's disease:
   - Dementia
   - Variations in the onset, in the presentation, or in the clinical course
   - May be made in the presence of a second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia
   - Should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable cause

McKhann *et al.*[29].

Vascular Dementia

Vascular dementia is a dementia caused by different forms of cerebrovascular disorder (CVD)[9,10], most often stroke and ischaemic white matter lesions (WMLs). The Hachinski Ischemic Score[11] was the most widely used instrument for the diagnosis of vascular dementia, or rather multi-infarct dementia (MID), from the 1970s to the early 1990s. It consists of a symptom checklist that incorporates some of the symptoms that are believed to be essential in MID, such as abrupt onset, stepwise deterioration, fluctuating course, a history of stroke, and focal neurological symptoms and signs. The assumption was that MID was caused

by embolic phenomena, so that the onset of the clinical condition would be sudden and acute. Subsequent further emboli would produce other sudden deteriorations, perhaps followed by some improvement as areas of brain oedema resolved and some function was restored.

WMLs refer to the histopathological picture of diffuse demyelination with incomplete infarction in subcortical structures of both hemispheres, and arteriosclerotic changes with hyalinization or fibrosis of the small penetrating arteries and arterioles in the white matter[9]. These lesions may appear as low-density areas on computed tomography (CT) scans and as hyperdense areas on magnetic resonance imaging (MRI). The cognitive decline in subjects with WMLs has been suggested to be caused by a disconnection of subcortical–cortical pathways, producing a decline in abilities related to subcortical or frontal lobe structures.

Memory impairment is mandatory for the diagnosis of vascular dementia in ICD-10, DSM-III-R and DSM-IV. This is not ideal to describe the cognitive dysfunction in vascular dementia, where intellectual impairment may be substantial while memory dysfunction is mild[12]. The ICD-10 requires that "deficits in higher cognitive functions are unevenly distributed" and DSM-III-R that there is "a patchy distribution of deficits (i.e. affecting some functions, but not others) early in the course". The latter was, however, no longer included in the DSM-IV.

Although stroke increases the risk of developing dementia several-fold[13,14] the contributions of a stroke or an infarct to the clinical symptoms of dementia are not always easy to elucidate. Stroke may be the main cause of dementia in an individual, it may be the event that finally overcomes the brain's compensatory capacity in a subject whose brain is already compromised by Alzheimer pathology, albeit not yet clinically manifest, and in many instances minor manifestations of both disorders which individually would not be enough to produce dementia may produce it together[15]. Sometimes the presence of stroke in a patient with AD may be coincidental. Most criteria leave it to the clinician to make the decision whether the cerebrovascular disease "may be judged to be aetiologically related to the dementia" (ICD-10, DSM-III-R, DSM IV).

In most criteria the definition of CVD is based on history or findings of focal neurological upper motor neuron symptoms/signs, or brain imaging findings of CVD. DSM-IV (Table 36.5) gives examples of signs, while the ICD-10 (Table 36.6) specifically requires that at least one should be: (1) unilateral spastic weakness of the limbs; (2) unilateral increased tendon reflexes; (3) extensor plantar response; or (4) pseudobulbar palsy.

The DSM-IV specifies that there should be signs *and* symptoms *or* laboratory evidence indicative of CVD (e.g. multiple infarctions involving the cortex and underlying white matter) that are judged to be aetiologically related to the disturbance, while ICD-10 requires that there should be evidence from history, examination *or* tests of a significant CVD, which may be reasonably judged to be aetiologically related to the dementia (e.g. history of stroke or evidence of cerebral infarction). In the National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS–AIREN) criteria[10] (Table 36.7), a diagnosis of probably vascular dementia requires that focal signs consistent with stroke *and* relevant CVD by brain imaging should be present. Tatemichi, one of the authors of the NINDS–AIREN criteria, and his colleagues published a modified version[16], in which this criterion was changed to focal signs consistent with stroke *or* relevant CVD by brain imaging. The first criterion is probably too strict and underestimates the occurrence of VaD; the latter criterion may be too broad. The NINDS–AIREN criteria recommend that a diagnosis of "possible" vascular dementia may be made in the presence of dementia with focal neurological signs in patients in whom brain imaging studies are missing; or in the absence of a clear temporal relationship between dementia and stroke; or in patients with subtle onset and variable course. This means that if CVD is present in a patient with dementia, VAD is likely to be diagnosed, which might overestimate the occurrence of this type of dementia. Furthermore, the interpretation of a single stroke leading to dementia probably differs between centres, and may be one reason for the disparate results regarding the prevalence of vascular dementia.

Table 36.5 DSM-IV Vascular dementia

A/B	General criteria for dementia
C	Focal neurological signs and symptoms, e.g:
	Exaggeration of deep tendon reflexes
	Extensor plantar response
	Pseudobulbar palsy
	Gait abnormalities
	Weakness of an extremity
	or
	Laboratory evidence of cerebrovascular disease, e.g.
	Multiple infarctions involving cortex and underlying white matter that are judged to be etiologically related to the disturbance
D	Do not occur exclusively during delirium

American Psychiatric Association[2].

Table 36.6 ICD-10 Criteria for vascular dementia (adapted)

G1	The general criteria for dementia (G1–G4) must be met
G2	Deficits in higher cognitive function are unevenly distributed, with some findings affected and others relatively spared
G3	There is clinical evidence of focal brain damage, manifest as *at least* one of the following:
	(1) Unilateral spastic weakness of the limbs
	(2) Unilaterally increased tendon reflexes
	(3) An extensor plantar response
	(4) Pseudobulbar palsy
G4	There is evidence from the history, examination, *or* tests of a significant cerebrovascular disease, which may reasonably be judged to be etiologically related to the dementia

World Health Organization[3].

Table 36.7 The NINDS–AIREN criteria

Probable Vascular Dementia
1. Dementia
2. Cerebrovascular disease
   (a) Focal signs consistent with stroke
   and
   (b) Relevant CVD by brain imaging:
   Multiple large-vessel infarcts
   Single strategically placed infarct
   Multiple lacunes (basal ganglia, white matter)
   Extensive periventricular white matter lesions
3. Relationship between (1) and (2):
   (a) Dementia onset within 3 months following stroke
   (b) Abrupt deterioration in cognitive functions
   (c) Fluctuating stepwise progression

Possible Vascular Dementia
1. Dementia
2. Cerebrovascular disease
   Focal signs consistent with stroke
3. Absence of relationship between (1) and (2)
   (a) Dementia onset more than 3 months following stroke
   (b) Subtle onset or variable course

The temporal relationship between stroke and onset of dementia is often thought to strengthen the possibility that the two disorders are aetiologically related. The NINDS–AIREN criteria suggest an arbitrary limit of 3 months for onset of dementia after stroke. However, a stroke which occurred years before may still indicate the presence of CVD.

VAD may be underdiagnosed, as sometimes the onset is insidious, the course gradual, the infarctions clinically silent and the infarcts not detectable by CT of the brain[17,18]. VAD may be overdiagnosed, as the presence of stroke, WMLs or other CVD does not necessarily mean that they are the cause of the dementia[17]. Often AD becomes a diagnosis by exclusion, and the diagnosis of VAD will be assigned if the patient has a history of CVD. This leads to a situation where the dementias will not infrequently be divided into one group with stroke and one without, giving negative associations between risk factors for stroke and AD, and positive associations with VAD[17].

Even the histopathological diagnoses of AD and VaD are uncertain. Extensive histopathological signs of AD[19,20] and VAD[19,21] have been found in persons who show no clinical signs of dementia during life. A considerable proportion of subjects fulfilling the diagnosis of probable NINCDS–ADRDA criteria for AD or probable NINDS–AIREN for VAD have mixed pathologies[22,23]. CVD may increase the possibility that individuals with AD lesions in their brains will express a dementia syndrome[24], but some workers have suggested that there may be a causal link between AD and VAD[25].

Frontotemporal Dementia

Frontotemporal dementia is a neurodegenerative disease characterized by neuronal loss in the frontal and temporal lobes. Criteria for frontotemporal dementia was proposed by the Lund and Manchester Groups in 1994[26], and revised in 1998[27]. The latter describes five core diagnostic features that must be present: (a) insidious onset and gradual progression; (b) early decline in social interpersonal conduct; (c) early impairment in regulation of personal conduct (e.g. social disinhibition); (d) early emotional blunting (such as inertia and loss of volition); and (e) early loss of insight. It also includes supportive diagnostic features, which are not present in all patients: (a) behavioural disorder; (b) speech and language alterations (economical output, reduced number of words, aspontaneity, press of speech, stereotypy, echolalia, mutism, perseveration); (c) physical signs (primitive reflexes, incontinence, akinesia, rigidity, tremor, low or labile blood pressure); (d) investigations showing impairment in frontal lobe tests in the absence of severe amnesia, aphasia or perceptual disorder, normal EEG, and frontal or anterior temporal abnormality on CBF. Other common symptoms are stereotyped behaviour and motor perseverations. Cognitive deficits occur mainly in attention, abstraction, planning and problem solving, while memory is relatively well-preserved in the early phase[27]. In DSM-IV and ICD-10, this type of dementia is classified under the heading Dementia due to Pick's disease, while Pick's disease is a subtype of frontotemporal dementia in the criteria from Neary *et al*[27]. According to the ICD-10, the general criteria for dementia should be met, onset should be slow with steady deterioration, memory and parietal lobe functions should be relatively preserved in the early stages, and at least two symptoms should be either emotional blunting, coarsening of social behaviour, disinhibition, apathy or restlessness, and aphasia. The problem with the emphasis on memory impairment in the general criteria for dementia in this disorder is evident.

Two other clinical syndromes of frontotemporal degeneration are progressive nonfluent aphasia and semantic dementia, which are disorders of language. Patients with Alzheimer's disease, vascular dementia, and some other brain disorders may also exhibit symptoms of the frontal lobe type during the course of their disorders.

Lewy Body Dementia

Lewy body disease is a neurodegenerative dementia characterized by Lewy body formation in the brain stem and cerebral cortex. It has been reported that as much as 20% of demented patients coming to autopsy exhibit these changes. Criteria for Lewy body dementia are lacking in DSM-IV and ICD-10, but were proposed by McKeith *et al*[28] in 1992. These include: (a) fluctuating cognitive impairment affecting both memory and higher cortical functions; (b) at least one of (i) visual and/or auditory hallucinations, (ii) mild spontaneous extrapyramidal features (mainly rigidity and hypokinesia) or a neuroleptic sensitivity syndrome (i.e. exaggerated adverse response to standard doses of neuroleptic medications), or (iii) repeated unexplained falls and/or transient clouding or loss of consciousness; (c) despite the fluctuating pattern the clinical features persist over a long period of time; (d) exclusion of any underlying physical illness adequate to explain the fluctuating cognitive state, and of past history of stroke or ischaemic brain damage on brain imaging. The clinical presentation often also includes paranoid ideations and depression.

Subcortical Dementia

A special subtype of dementia is subcortical dementia. This type of dementia is seen in subcortical disorders, such as Parkinson's disease with dementia, Huntington's disease, supranuclear palsy, Lewy body disease and subcortical ischaemic WMLs. The dominating symptoms are psychomotor retardation, emotional bluntness, akinesia and slight memory disturbance, which may be helped by cues.

Secondary Dementias

Secondary dementias are caused by conditions with a known aetiology where dementia is generally not a core symptom, but may occur in some patients. Traditionally, vascular dementia is not classified among the secondary dementias, while subdural haematomas, normal pressure hydrocephalus, Creutzfeldt–Jakob disease, brain tumours, metabolic disorders and deficiency states are treated as secondary dementias.

Cross-national Inter-rater Reliability of Dementia Diagnosis

Daniel W. O'Connor

Monash University, Melbourne, Australia

DSM-IV[1], ICD-10[2] and other glossaries have proved successful in promoting a common approach to psychiatric diagnosis. In field trials of DSM-III-R, for example, psychiatrists achieved concordance rates for diagnosing dementia of 0.91, where 1.0 represents complete agreement[3].

It cannot be assumed, however, that similar performances will be achieved in "real world" practice. Most studies of diagnostic reliability involve assessments by experienced clinicians of cooperative, physically healthy old people who are either "normal" controls or "pure cases" of dementia. In reality, cognitive function lies on a spectrum and assessment is often complicated by limited education, deafness, poor vision, physical illness, anxiety or depression.

In a study of five research teams in Australia, Germany, The Netherlands, the UK and the USA, each centre contributed 20 written vignettes of elderly persons encountered in clinics or community surveys[4]. No exclusions were made because of medical, neurological or psychiatric complications. The vignettes were brief and highly structured. The contents included subjects' demographic details, medical and psychiatric history, abbreviated cognitive test results and an informant's report of cognitive, personal and social performance.

When 13 researchers applied DSM-III-R criteria to the 100 vignettes, within-team levels of diagnostic agreement were high, ranging from kappa 0.72 in the centre with the least joint training to 0.86 in the centre with most. Between-team agreement was lower but still acceptable, with kappas ranging from 0.74 to 0.83. Some elements of DSM-III-R were easier to apply consistently than others. Mean percentage agreement was highest for social and occupational dysfunction (94%) and lowest for impairment of higher cortical function (87%). Concordance was also significantly higher for cognitively intact (98%) and severely impaired (96%) persons than for those with minimal (80%) and mild (82%) degrees of dementia.

DSM-IV[1], ICD-10[2] and other glossaries have proved successful in promoting a common approach to psychiatric diagnosis. In field trials of DSM-III-R, for example, psychiatrists achieved concordance rates for diagnosing dementia of 0.91, where 1.0 represents complete agreement[3].

It cannot be assumed, however, that similar performances will be achieved in "real world" practice. Most studies of diagnostic reliability involve assessments by experienced clinicians of cooperative, physically healthy old people who are either "normal" controls or "pure cases" of dementia. In reality, cognitive function lies on a spectrum and assessment is often complicated by limited education, deafness, poor vision, physical illness, anxiety or depression.

In a study of five research teams in Australia, Germany, The Netherlands, the UK and the USA, each centre contributed 20 written vignettes of elderly persons encountered in clinics or community surveys[4]. No exclusions were made because of medical, neurological or psychiatric complications. The vignettes were brief and highly structured. The contents included subjects' demographic details, medical and psychiatric history, abbreviated cognitive test results and an informant's report of cognitive, personal and social performance.

When 13 researchers applied DSM-III-R criteria to the 100 vignettes, within-team levels of diagnostic agreement were high, ranging from kappa 0.72 in the centre with the least joint training to 0.86 in the centre with most. Between-team agreement was lower but still acceptable, with kappas ranging from 0.74 to 0.83. Some elements of DSM-III-R were easier to apply consistently than others. Mean percentage agreement was highest for social and occupational dysfunction (94%) and lowest for impairment of higher cortical function (87%). Concordance was also significantly higher for cognitively intact (98%) and severely impaired (96%) persons than for those with minimal (80%) and mild (82%) degrees of dementia.

Agreement was higher for "yes–no" DSM-III-R diagnoses than for the multilevel Clinical Dementia Rating (CDR) scale, in which six domains (memory, orientation, judgement, community affairs, home and hobbies, and personal care) are each rated on a five-point scale[5]. Kappa levels ranged from 0.61 to 0.76 within teams and from 0.50 to 0.69 between teams. Personal care was rated most consistently (85% mean agreement) and community affairs least so (74%). As with DSM-III-R, concordance was higher for cognitively intact (95%) and severely impaired (84%) persons than for those with minimal (78%) and mild (68%) dementias.

Univariate analyses of CDR ratings pointed to lower agreement levels for persons described as physically ill, deaf, partially sighted, anxious or depressed. However, multivariate analysis detected only two main effects: dementia severity and physical illness. Other variables made no significant independent contribution.

These findings suggest that dementia can be diagnosed with acceptable reliability in community surveys. Agreement is likely to be higher, though, when teams train intensively and use instruments that require simple "yes–no" choices. The reduction in agreement associated with physical illness is important given the high co-morbidity of physical and mental illness in representative elderly populations.

Early Detection

Scott Henderson

Centre for Mental Health Research, The Australian National University, Canberra ACT 0200, Australia

IS EARLY DETECTION IMPORTANT?

Why try to detect dementia early in its course? Since the advent of technologies for the early detection of disease, it has become important to ask whether early recognition is worthwhile, and for whom. Can it be shown that a lower level of morbidity is achieved in a population that has been screened, compared to others that were not screened? Is the quality of life of cases improved by their early diagnosis; or could early detection of dementia "seriously damage your health", as has been found for other disorders[1]? For a start, evaluation of the early detection of dementia would have to take note of the 10 principles of screening, as listed by Wilson and Jungner[2]. These include the requirement that there be an accepted form of treatment for persons once detected, that facilities for diagnosis and treatment be available to the population being screened, and that a suitable test be available for detecting the disease in its early stages. Clearly, screening for early dementia is a procedure where none of these requirements has yet been met.

Cooper and Bickel[3] have nevertheless indicated some of the advantages that screening or early detection could bring. They point out, first, that the biggest gap between those receiving specialist psychiatric care and the total volume of morbidity in a general population is amongst its elderly; and that mental disorders in this age group are probably under-recognized by general physicians. Second, a proportion of cases detected as dementia have reversible conditions such as depressive disorder, normal pressure hydrocephalus, metabolic disorders or brain tumours. Third, early detection can be a preliminary not to curative treatment but "to intervention aimed at reducing disability and postponing the need for institutional care". Such intervention is well placed with the general practitioner and the person's family. It can then be added that, for the general practitioner, the advantages of early detection are appreciable: the possible causes of the cognitive or behavioural deterioration may need to be pursued. Where co-morbidity emerges, as it commonly will, the physician's awareness that dementia is present will prove useful in assessment and continuing management; and the presence of dementia may influence the choice of medication.

There is one further reason for early detection, although this is not to the individual patient's immediate benefit. For research on dementia, it is of great importance to know about the earliest symptoms and signs before these become buried by the dementia itself. Without this information, and without knowing the clinical course of mild cases, it may not be possible to improve the specificity of screening, and to distinguish between mild cognitive decline and normal ageing[4]. For population-based research, where some early cases will inevitably be identified, Brayne *et al.*[5] recommend that a two-stage design should ideally be used, along with a third assessment that serves as a gold standard: evidence of progression of the dementia; or neuropathology at post mortem.

HOW IS EARLY DETECTION ACHIEVED?

Early detection will usually mean the dementia is of only mild severity. It is an advantage, therefore, that the diagnostic criteria for mild dementia have been specified in both ICD-10[6] and DSM-IV[7]. In ICD-10, the declining memory and information processing causes impaired performance in daily living, but not to a degree that is incompatible with independent living. Explicit criteria are given for the diagnosis of mild dementia.

Early detection can be carried out at three levels: in the community, in primary care settings, and in hospitals. In the community, screening is conducted only as part of research studies, and has not yet been used in a way similar to other routine screening for disease. In primary care, early detection is at present conducted informally and is based largely on the initiative and clinical skill of the practitioner. It is not clear what most commonly prompts the physician into considering a diagnosis of early dementia. Rarely it would be, say, all persons aged 70 years and over consulting in a given period, but rather those who prompt the physician's concern. Commonly, it is the patient's family who have first detected a deterioration in cognition or behaviour. The present consensus is that, in the absence of some indication, efforts to detect early dementia in general practice are unwarranted. But there may be a place for routinely obtaining a base-line measure of cognitive performance against which subsequent assessments can be placed. There is as yet no place for annual repetition of the assessment.

Tests for Early Detection of Dementia

In hospitals and clinics, the realities of clinical practice are that early detection of dementia is achieved in one of two ways. In the more common style, the clinician obtains a history from others that a *decline* in cognitive performance and/or behaviour has taken place. To this is added some non-systematic cognitive assessment of the patient, leading to a conclusion on whether or not early dementia is present. Clearly, other clinical features,

such as cerebrovascular disease, would commonly play a part in this.

In the second situation, the assessment is formal and partly quantitative. A large number of standardized clinical instruments and neuropsychological tests for this are now available. They are described in Section DIII of this volume. For the purpose of *early* detection, two points need to be emphasized. Firstly, some of the tests are open to educational or cultural bias, so that they can generate false-positive results in some sociodemographic contexts, possibly to the patient's detriment. Secondly, in this writer's opinion, many tests are focused on cognitive function, ignoring changes in behaviour—yet the latter are an important clue to early dementia. The Psychogeriatric Assessment Scales developed by Jorm *et al.*[8] have gone some way to redress this imbalance (*see* Chapter 27).

Limitations

To detect dementia early in its course, and to do so with a high level of accuracy in different social and educational groups, is not a straightforward task. The only means currently available are those clinical instruments described in Section DIII. There is no biomedical test with both portability and greater accuracy than these instruments. The clinical instruments all have a number of limitations. First, the mental status questionnaires are brief, and can act only as screening instruments that sort individuals into different levels of probability of being a case of dementia. A questionnaire cannot be expected to do more than this. Second, the instrument must be acceptable; yet elderly people may dislike extensive cognitive testing, particularly if it shows them up as defective in performance. Third, whether it is a brief questionnaire or a clinical examination, the reliability and validity have to be high. The latter means achieving good levels of sensitivity and specificity. Fourth, and closely related to validity, there is the problem of bias against low intelligence or poor education. It is highly likely that this causes some false-positives to appear in the course of screening.

Whatever the method used for early detection, there are three further issues to consider. Not all the cases detected will progress[9,10] and it is hard to predict to whom this will happen.

ORGANIC DISORDERS

Rosenman[11] found very poor predictive validity for five well-established methods for making this diagnosis. Cooper and Bickel[3] argue that there are no good grounds for asking elderly persons to subject themselves to extensive investigations when some will undergo no further deterioration. A further impediment is the cost and service burden from investigating all the possible cases of dementia generated from a national screening programme. Eastwood and Corbin[12] have argued that the cost would be prohibitive. This is likely to be the case even for the older section of the community, where the frequency of secondary dementias is known to be lower than in younger adults. Lastly, there may be unexpected adverse consequences of screening. The belief may be false that early detection can contribute to prevention. O'Connor *et al.*[13] found, unexpectedly, that screening for early or mild dementia increased the likelihood of entry into residential care.

WHAT POSSIBLE SOLUTIONS ARE THERE?

Routine screening for dementia at the community level cannot yet be defended. What is required instead is work to evaluate its impact in the manner advocated by Cooper and Bickel[3]. These authors have emphasized the need for research into the feasibility and effectiveness of early detection as a first step towards preventive action. They also argue that programmes for early detection will be successful only if they are incorporated into the work of general practitioners, community nurses and other health professionals. It is there, and not the total community of elderly, where early detection needs first to be attempted and evaluated to see what benefits, if any, it brings.

At a technical level, it has to be accepted that early detection of cognitive decline or dementia by brief screening methods has at least two unavoidable imperfections: first, there will be some error, whereby the screening test misclassifies a proportion of individuals; second, some of this error will be attributable to low intelligence in the respondent, or educational bias in the test. Since both of these are likely to produce false-positives rather than negatives, the problem can usually be overcome by more detailed clinical assessment and history in a two-phase design. In research settings, another desirable strategy in early detection is to have a second assessment after an appropriate lapse of time. This is the most certain way to ensure that deterioration has indeed taken place, and that it has progressed. Early detection of dementia is currently dependent on clinical information and on cognitive performance related to daily life. Assessment of this is now remarkably satisfactory, although the validity of the main clinical instruments has yet to be demonstrated in community instead of hospital samples. Because dementia has very explicit clinical manifestations and associated impairments, its early detection is likely to be by clinical means for some time to come. For the present, early detection brings no benefit to the elderly in the general population. But the situation may soon change in the face of current advances in the molecular biology of Alzheimer's disease, where it is conceivable that early detection may become justified for genetically high-risk individuals for whom a pharmacological intervention could be beneficial[14]. It is from these advances that far-reaching consequences for clinical practice are now imminent.

Dementia Epidemiology: Prevalence and Incidence

A. F. Jorm

Centre for Mental Health Research, The Australian National University, Canberra, Australia

Prevalence is the proportion of cases of a disease present in a population at any one time, while incidence is the rate of occurrence of new cases over a given period of time, usually 1 year. Prevalence is a function of both the incidence of disease and its duration: the prevalence of a disease will rise if the rate of new cases increases or if the average case survives longer. Prevalence is useful for assessing the likely need for service provision. However, for purely scientific purposes, such as assessing risk factors, incidence is preferred over prevalence. The reason is that any differences between groups in prevalence may be due to differences in either incidence or disease duration.

The notions of prevalence and incidence are based on the assumption that a population can be neatly divided into cases and non-cases. However, for dementia this division is not straightforward. There is a gradation from normal cognitive ageing through to severe dementia, without clear breaks to define where normality ends and dementia begins. The threshold for dementia is usually defined in terms of interference with daily living, but even this is a fuzzy boundary. Furthermore, prevalence and incidence studies typically examine different levels of severity, described as "mild", "moderate" or "severe", but these descriptors are not always used consistently to divide up the continuum of severity. Various diagnostic criteria for dementia are known to divide the continuum in different ways, which can result in very different prevalence and incidence rates. For example, Erkinjuntti *et al.*[1] examined the rates of dementia in the same sample using six different sets of diagnostic criteria. They found that the percentage with dementia varied from 3.1% using the ICD-10 criteria to 29.1% using DSM-III. Thus, there are no "true" prevalence or incidence rates for dementia, but rather various rates dependent on the definition of dementia used.

PREVALENCE OF DEMENTIA

The number of prevalence studies is now very large and several meta-analyses have been carried out to pool the data for those that give rates for specific age groups (e.g. 65–69 years). The first meta-analysis, by Jorm *et al.*[2], involved fitting a statistical model to data from 22 studies published between 1945 and 1985. They found that methodological differences between studies contributed to variation in prevalence rates. For example, studies that used a broad definition of dementia (to include all cognitive impairment) had rates 64% higher than those using a more narrow definition. They fitted an exponential statistical model to the data[2]. The essence of this model is that prevalence rises exponentially with age, doubling every 5.1 years, but the actual rates differ from study to study. Although there were differences between studies, it is possible to derive average rates across studies. These are shown in column 1 of Table 38.1. The exponential model is an adequate description up to age 90 but should not be applied above that age. If prevalence continued to double every 5.1 years above age 90, it would soon be greater than 100%, which is impossible. This limitation of the exponential model has led some researchers to use the logistic model, in which prevalence at first rises steeply, but then levels out to a maximum of 100%[3]. For prevalence rates of 0–50% the exponential and logistic curves are difficult to distinguish, and the exponential curve may be preferred because of its simplicity.

The second meta-analysis involved a pooling of data from 12 European studies dating 1980–1990, which used DSM-III or equivalent criteria[4]. This meta-analysis did not involve fitting a statistical model to the data or testing for the effects of methodological differences. Rather, the researchers simply divided the data from each study into 5 year age groups and pooled them. The results are shown in column 2 of Table 38.1. Despite the differences in approach, the results are remarkably close to those of Jorm *et al.*[2].

A third meta-analysis was carried out by Ritchie and Kildea[5] (this superseded an earlier meta-analysis by Ritchie *et al.*[6], which will not be described here). They were particularly interested in what happens to prevalence in extreme old age, in particular whether dementia is inevitable if a person lives long enough. Ritchie and Kildea[5] pooled data from nine studies that included samples of elderly people aged over 80. These data are shown in column 3 of Table 38.1 and are very similar to the earlier meta-analyses up to age 90. Ritchie and Kildea[5] fitted various curves to

Table 38.1 Prevalence rates (%) for dementia from three meta-analyses

Age group	Meta-analysis		
	Jorm *et al.*[2]	Hofman *et al.*[4]	Ritchie and Kildea[5]
60–64	0.7	1.0	—
65–69	1.4	1.4	1.5
70–74	2.8	4.1	3.5
75–79	5.6	5.7	6.8
80–84	11.1	13.0	13.6
85–89	23.6*	24.5*	22.3
90–94	—	—	33.0
95–99			44.8

* Rates for ages 85+.

the data, including exponential and logistic models. The best fit was by a modified logistic curve in which prevalence levelled off at around 40% at age 95. The authors concluded that dementia is not inevitable in extreme old age. However, this conclusion has been criticized by McGee and Brayne[7] because it was based on prevalence rather than incidence data. A decrease in survival with dementia in very old age could explain the flattening of the age-curve that was observed.

PREVALENCE OF ALZHEIMER'S DISEASE AND VASCULAR DEMENTIA

The clinical diagnosis of Alzheimer's disease and vascular dementia in community surveys involves additional problems beyond those in diagnosing global dementia, so such studies have been fewer. Nevertheless, several meta-analyses have attempted to integrate data on the issue.

The original meta-analysis of Jorm *et al.*[2] also examined seven studies that gave age-specific data on Alzheimer's disease and vascular dementia. One study could not be fitted well by the exponential model, but the remaining six could. The prevalence of Alzheimer's was found to double every 4.5 years of age, while vascular dementia doubled every 5.3 years. In other words, the rise with age was steeper for Alzheimer's disease.

The pooling of data from European studies also examined specific dementing diseases[8]. The pooled prevalence rates for Alzheimer's disease from six studies were: 30–59 years, 0.02%; 60–69 years, 0.3%; 70–79 years, 3.2%; and 80–89 years, 10.8%. It was not possible to arrive at pooled rates for vascular dementia because of the variation across studies.

Later, Corrada *et al.*[9] fitted a logistic model to data from 15 studies giving age-specific data on prevalence of Alzheimer's disease. They found considerable variation in rates between studies depending on the methodology used. However, the underlying trend was for an 18% increase in the odds for Alzheimer's disease with every year of age.

The most recent meta-analysis was carried out by the US General Accounting Office[10] in response to controversy in that country about the number of people with Alzheimer's disease. A logistic curve was fitted to data from 18 studies with predominantly White populations. The data were grouped by sex and severity level of the dementia and are shown in Table 38.2. It can be seen that the results vary, depending on severity, and that females have a higher prevalence than males.

Table 38.2 Prevalence rates (%) for Alzheimer's disease according to a meta-analysis by the US General Accounting Office[10]

	All severity levels		Moderate–severe cases	
Age	Men	Women	Men	Women
65	0.6	0.8	0.3	0.6
70	1.3	1.7	0.6	1.1
75	2.7	3.5	1.1	2.3
80	5.6	7.1	2.3	4.4
85	11.1	13.8	4.4	8.6
90	20.8	25.2	8.5	15.8
95	35.6	41.5	15.8	27.4

INCIDENCE STUDIES

Incidence studies are much rarer than prevalence studies because they require longitudinal data and large sample sizes to arrive at age-specific rates. It is only fairly recently that sufficient studies have become available to permit meta-analysis.

Two meta-analyses have been published at around the same time. The first of these, by Jorm and Jolley[11], used data from 23 published studies. The incidence of both dementia and Alzheimer's disease was found to increase exponentially with age up to

Table 38.3. Incidence rates (%) for dementia from meta-analyses by Jorm and Jolley[11] and Gao *et al.*[12]

	Jorm and Jolley[11]				Gao *et al.*[12]
Age group	Europe (mild+)	Europe (moderate+)	USA (moderate+)	East Asia (mild+)	12 studies
60–64	—	—	—	—	0.11
65–69	0.91	0.36	0.24	0.35	0.33
70–74	1.76	0.64	0.50	0.71	0.84
75–79	3.33	1.17	1.05	1.47	1.82
80–84	5.99	2.15	1.77	3.26	3.36
85–89	10.41	3.77	2.75	7.21	5.33
90–94	17.98	6.61	—	—	7.29
95+	—	—	—	—	8.68

Mild+ results from USA and Moderate+ results from East Asia are missing from the table because insufficient data were found in the literature.

Table 38.4 Incidence rates (%) for Alzheimer's disease from meta-analyses by Jorm and Jolley[11] and Gao *et al.*[12]

	Jorm and Jolley[11]					Gao *et al.*
Age group	Europe (mild+)	Europe (moderate+)	USA (mild+)	USA (moderate+)	East Asia (mild+)	8 studies
60–64	—	—	—	—	—	0.06
65–69	0.25	0.10	0.61	0.16	0.07	0.19
70–74	0.52	0.22	1.11	0.35	0.21	0.51
75–79	1.07	0.48	2.01	0.78	0.58	1.17
80–84	2.21	1.06	3.84	1.48	1.49	2.31
85–89	4.61	2.26	7.45	2.60	3.97	3.86
90–94	9.66	4.77	-	-	-	5.49
95+	-	-	-	-	-	6.68

Moderate+ results from East Asia are missing from the table because insufficient data were found in the literature.

90 years, with no sign of levelling off. The incidence of vascular dementia showed similar trends, but the actual rates varied greatly from study to study. There was no sex difference in dementia, but women tended to have a higher incidence of Alzheimer's disease in very old age, and men a higher incidence of vascular dementia at younger ages. There were also regional differences, with East Asian countries having a significantly lower incidence of dementia than Europe, and also tending to have a lower incidence of Alzheimer's disease. Tables 38.3 and 38.4 summarize the results for different regions and levels of severity.

The second meta-analysis, by Gao *et al.*[12], involved only the subset of 12 studies that used DSM-III criteria for dementia and NINCDS–ADRDA criteria for Alzheimer's disease. The data were fitted with a logistic model and a levelling of the rate of increase with age was found. Women were found to have a higher incidence of Alzheimer's disease than men. The estimated incidence rates are also shown in Tables 38.3 and 38.4. It can be seen that the rates of Gao *et al.*[12] are different from those of Jorm and Jolley[11] and the two meta-analyses came to different conclusions about whether there is a levelling in the rise with age. The difference arises because Gao *et al.*[12] pooled data from different regions and different levels of severity. Their rates fall in between those of Jorm and Jolley[11] for Mild+ and Moderate+ dementia. Deviations from an exponential rise can result if the studies contributing cases at the upper ages are examining milder dementia or are from regions with a lower incidence.

CONCLUSIONS

The prevalence and incidence of dementia rise exponentially with age up to age 90. There is no consensus about what happens at extreme ages, because of the limited data available, but some levelling in the rise is a possibility. Women probably have a higher prevalence and incidence of Alzheimer's disease. Conversely, men may be at greater risk of vascular dementia. There appear to be important regional differences, although the proper investigation of these requires studies with identical methodologies in the various sites.

Case-control Studies

Scott Henderson

NHMRC Psychiatric Epidemiology Research Centre, Australian National University, Canberra, ACT 0200, Australia

The case-control study is aimed at aetiology. Schlesselman[1] says that it has two distinctive features: it proceeds backwards from effect to cause by trying to identify exposures or other factors that led to a given disorder; and it uses a control or comparison group without the disorder, so that a causal effect for a given exposure can be supported or refuted. The first of these features is really what a clinician does in daily practice when taking a history, but as a rule, the clinician does not go on to determine how many *normal* persons have had the same exposure. The strength of the case-control method lies in these two features. It is on the basis of them that the fundamental comparison in the case-control study lies: the frequency of an exposure in the cases, and the frequency in the controls. Such a comparison is disarmingly simple, mainly because of the biases that can bring about misleading results. Some readable accounts can be found in Cole[2], Lilienfeld and Lilienfeld[3], Feinstein[4] and Anthony[5]. A non-technical overview has been set out by Henderson[6]. An entire issue of *Epidemiologic Reviews* devoted to the case-control method has provided an excellent conspectus of this powerful tool, including the diverse applications now being made of case-control designs for problem-solving in the health field, including evaluation of service interventions[7].

In case-control parlance, "exposure" refers not only to environmental exposures, but to other properties of the individual, such as a family history of a particular disease or some other personal attribute. To identify an exposure that may contribute to the onset of a disorder, the investigator has firstly to choose a number of candidate exposures. This may be based on theory, on speculation, or on a mindless search. The first of these is particularly desirable, because it means that from the start there is some plausible biological or psychosocial basis for the putative effect. Speculation can be the vehicle for a gifted insight. The atheoretical examination of a large array of factors is undesirable and carries the risk of capitalization on chance.

CONDUCTING A CASE-CONTROL STUDY

There are five issues that deserve close attention:

1. The cases should be newly diagnosed, not ones which have been known for some time; and they should be representative of all incident cases in the population. If longer-established cases were used, the findings might be related more to factors influencing survival or chronicity than to aetiology (see below).
2. The cases should include no errors in diagnosis, which would lead to misclassification and therefore errors in estimating the relative risk for exposures.
3. The controls should either be matched demographically or be similar in overall attributes. Much thought needs to be accorded to the source of the controls if misleading biases are to be avoided.
4. In obtaining information on exposures from cases and controls, as well as from their informants, it is likely that selection effects will operate, causing information bias. That is, people may selectively recall certain experiences, or selectively report what they do recall. A likely example is a history of past head injury in Alzheimer's disease, or any other situation where "effort after meaning" may operate. Ideally, the interviewers should themselves be blind to the purpose of the study, lest they unwittingly influence the information that they elicit.
5. A case-control study that has too few cases to provide a satisfactory estimate of risk is of little value. The sample size needed can be determined beforehand by establishing the minimum size of the effect to be demonstrated, and the frequency of exposure in the controls. The more the frequency of the exposure departs from 50% of the subjects, the more cases will be needed for an association to be shown.

The assessment of risk for an exposure is obtained by calculating its odds ratio as an approximation of the relative risk, and the 95% confidence intervals for that estimate (Schlesselman[1], p. 32 *et seq.*) (Henderson[6], p. 16 *et seq.*). An odds ratio of 1.0 means that the exposure occurs as often in cases as in controls. The confidence interval should keep the estimate above unity if the exposure is to be accorded attention. It is misleading to report odds ratios without also giving their confidence intervals. For example, an odds ratio of 1.7 with a 95% confidence interval of 0.9–2.5 should be seen as a negative finding, because the lower limit is below unity.

RESULTS OF CASE-CONTROL STUDIES OF DEMENTIA

Nearly all the case-control studies of dementia have been focused on Alzheimer's disease (AD). Within this diagnostic group, the studies have covered several categories, although not always making this explicit. The cases have often been heterogeneous in age of onset and, indeed, in age *since* onset. The latter introduces the problem of Neyman's bias[5] and factors related to survival after the onset of the dementia. In looking critically at case-control studies of dementia, their strengths and deficiencies can be seen by using the above points as a checklist, to assess the value that can be attached to each observation. Most studies have had only modest sample sizes. In case-control studies of AD, the

scientific significance of a result should rest on its replication by other workers on other samples; and on the development of biological evidence to support it as a risk factor in AD.

Risk and Protective Factors for Alzheimer's Disease

A comprehensive review of the evidence for a wide range of proposed risk factors, but also protective factors for AD, have been given by Jorm[8] and Henderson and Jorm[9].

Summarized, these are as follows:

Definite
- Age.
- Family history.
- Specific genetic mutations (for familial cases only).
- Apolipoprotein E ε4 allele on chromosome 19.
- Down's syndrome.

Awaiting confirmation
- Regional or ethnic differences.
- α-2 Macroglobulin gene.
- Head injury (interaction with apoE?).
- Previous depressive disorder.
- Herpes simplex virus.
- Cerebrovascular disease.

Unlikely
- Aluminium in drinking water.
- Diet.
- Industrial solvents.
- Life stress.
- Electromagnetic fields.

Possible protective factors
- Education, high premorbid intelligence or both.
- Anti-inflammatory drugs (NSAIDS).
- Oestrogen.
- Smoking.
- Moderate wine drinking.

For vascular dementia, the review by Skoog[10] lists the same risk factors as for stroke, namely hypertension, diabetes mellitus, advanced age, being male, smoking and cardiac disease. A number of recent case-control studies have suggested that vascular factors may have a part to play in AD. There are as yet no case-control studies of Lewy body or other less common dementias, although there is no impediment other than ensuring accuracy of ascertainment and recruitment of sufficient cases. The same applies to other under-researched areas of geriatric psychiatry, such as the psychoses of late onset, where case-control studies could throw much-needed light on pathogenesis.

It does seem justifiable to continue to search for environmental exposures and other risk factors for AD, for vascular dementia and possibly the rarer dementias. Case-control research may in this way contribute not only to understanding their aetiology, but to finding preventive measures—the ultimate purpose of epidemiology. With the great expansion of the world's elderly, the social significance of this would be inestimable.

Results from EURODEM Collaboration on the Incidence of Dementia

LJ Launer[1], for the EURODEM Incidence Research Group*

[1]*Erasmus University Medical Centre, Rotterdam, The Netherlands, and National Institutes of Health, Bethesda, MD, USA*

In 1988, European investigators formed the EURODEM network to harmonize the protocols used in newly initiated population-based prospective studies on incident dementing diseases[1]. Incident studies succeeded the case-control studies based on prevalent cases that were conducted in the 1980s[2]. Studies based on incident cases are preferred to those based on prevalent cases, as the latter have several biases that affect the validity of their results[3]. Here we summarize the findings from the pooled EURODEM analyses on the frequency and risk for dementing disease in the elderly.

STUDY DESIGN

The pooled analyses are based on studies from Denmark[4], France[5], The Netherlands[6] and the UK[7]. The sample includes

Results from EURODEM Collaboration on the Incidence of Dementia

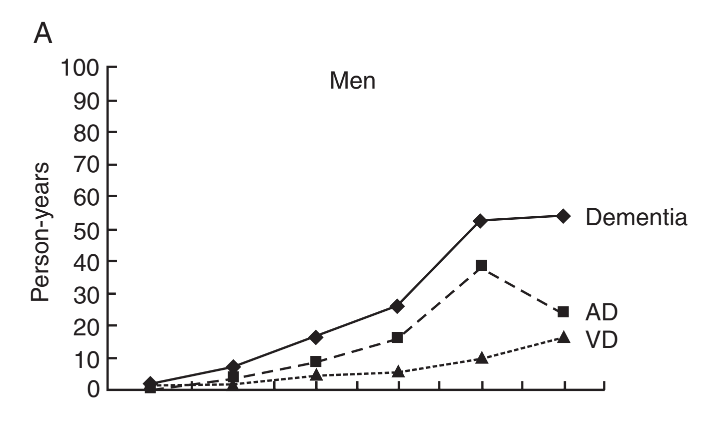
LJ Launer[1], for the EURODEM Incidence Research Group*

[1]*Erasmus University Medical Centre, Rotterdam, The Netherlands, and National Institutes of Health, Bethesda, MD, USA*

In 1988, European investigators formed the EURODEM network to harmonize the protocols used in newly initiated population-based prospective studies on incident dementing diseases[1]. Incident studies succeeded the case-control studies based on prevalent cases that were conducted in the 1980s[2]. Studies based on incident cases are preferred to those based on prevalent cases, as the latter have several biases that affect the validity of their results[3]. Here we summarize the findings from the pooled EURODEM analyses on the frequency and risk for dementing disease in the elderly.

STUDY DESIGN

The pooled analyses are based on studies from Denmark[4], France[5], The Netherlands[6] and the UK[7]. The sample includes



*Participants of the EURODEM Incidence Research Group: Department of Epidemiology and Biostatistics, Erasmus Medical School, The Netherlands (A. Hofman MD, L.J. Launer PhD, A. Ott MD, T. Stijnen PhD); Epidemiology, Demography, Biometry Program, National Institute on Aging, US (L.J. Launer PhD); Department of Psychiatry, Odense University, Denmark (K. Andersen MD, P. Kragh-Sorensen MD); Department of Psychiatry, Royal Liverpool University Hospital, UK (J.R.M. Copeland MD, M.E. Dewey PhD), INSERM Unit 330, France (J.F. Dartigues MD, L. Letenneur PhD); National Research Council Targeted Program on Ageing, Italy (L.A. Amaducci MD: now deceased); Institute of Public Health, Cambridge University, UK (C. Brayne MD); Department of Psychiatry, Zaragoza University (A. Lobo MD) and Department of Neurology, University of Navarra, Spain (J.M. Martinez-Lage MD).

528 incident dementia cases and 28 768 person-years of follow-up. As a common core, each study included a population-based cohort of persons aged 65 years and older living in the community and nursing homes. Samples were drawn from defined geographic areas and either include all eligible individuals or individuals randomly selected within predefined strata. All studies contributed to the pooled analyses baseline data and one follow-up panel conducted after a fixed interval of about 3 years. The cohorts exclude the prevalent cases identified at baseline.

Dementia cases were identified in a two-stage procedure, whereby the total cohort was screened and screen-positive subjects underwent a detailed diagnostic assessment that included a clinical exam, neuropsychological testing and an informant interview. Dementia and vascular dementia were diagnosed according to DSM-III-R criteria[8], Alzheimer's disease (AD) was diagnosed according to NINCDS–ADRDA criteria[9].

RESULTS

AD comprised approximately 70% of all cases. Incident rates for dementia and AD were similar across studies. There was an increase with age in the incidence of all dementia and in particular AD. At 90 years of age and older the incidence of AD was 63.5 (95% CI, 49.7–81.0) per 1000 person-years. However, compared to men, women had significantly higher rates of AD after age 85 years. At 90 years of age, the rate of AD per 1000 person-years was 81.7 (63.8–104.7) in women and 24.0 (10.3–55.6) in men (Figure 1a,b)[10]. This translated into a cumulative risk for 65 year-old women to develop AD at the age of 95 years of 0.22 compared to 0.09 for men. These sex differences were not found in vascular dementia: at 90 years of age, the incidence of vascular dementia was 15.9 (6.6–38.5) and 9.2 (4.3–19.6) per 1000 person-years in men and women, respectively.

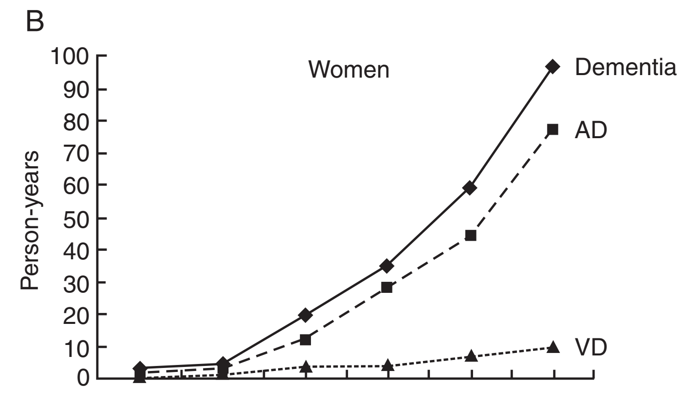


Figure 1 Incidence of dementia and major sub-types, Alzheimer's disease (AD) and vascular dementia (VD): EURODEM Studies. (A) men; (B) women

In addition to sex and age, we investigated the association of AD to four risk factors that had been previously investigated in case-control studies[1,2]. These risk factors were ascertained in a similar manner across studies. We found that low education increased the risk for dementia, specifically AD. However, the increased risk was detectable only in women: compared to those with high education, those with low education had a 4.3 (95% CI, 1.5–11.9) times, and those with middle education had a 2.6 (95% CI, 1.0–7.1) times increased risk for AD. There was no association of educational level to dementia among men[11]. Contrary to a previous EURODEM analysis based on case-control studies[2], we did not find an increased risk for AD associated with head trauma. Previous reports based on prevalent cases suggested an inverse association of smoking with the risk for AD[2]. In these current analyses based on incident cases, we found current smoking significantly *increased* the risk of AD. The risk associated with smoking was higher in men than women[1]. Finally, we found that the association of AD to family history in two or more family members was weaker (OR 1.59 95% CI, 0.78–3.26) than previously estimated on the basis of case-control studies[2].

SUMMARY

Because we had a large sample, we were able to investigate whether gender modified the risk for AD, the most common form of late-life dementia. We found that women not only had a higher risk for AD than men, but that the relations of education and smoking to the risk for AD were different in men and women. These findings suggest that the risk for AD is altered either by sex-related biological or behavioral factors or by differences in cumulative survival.

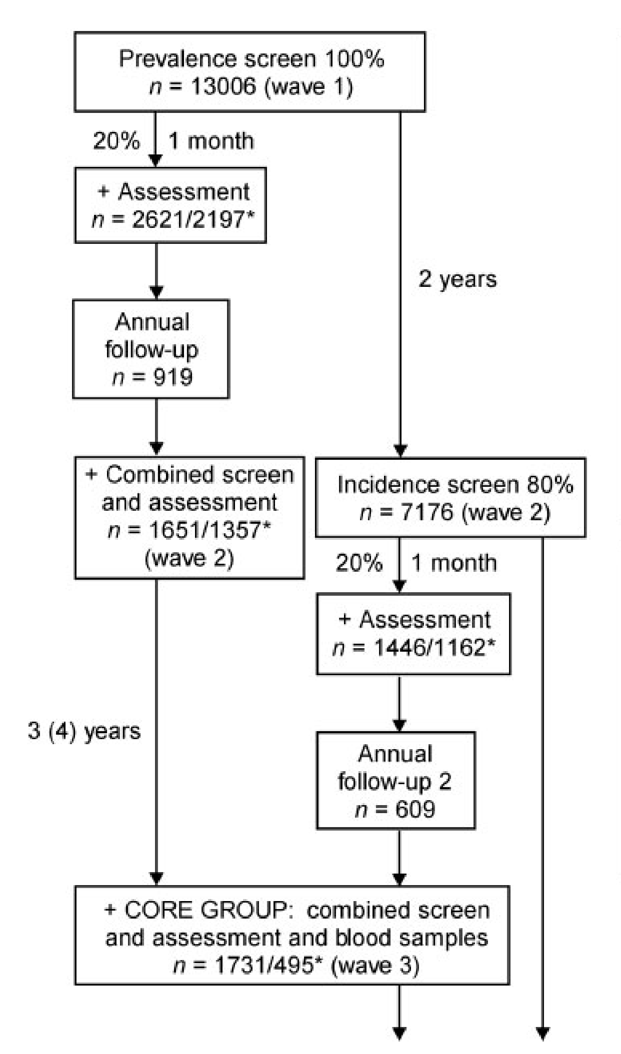
MRC/DoH Cognitive Function and Ageing Study

J. Nickson, C. F. M. McCracken and C. Brayne, on behalf of MRC CFAS

University of Cambridge, Cambridge, UK



The MRC Cognitive Function and Ageing Study (MRC CFAS) is a multi-centre prospective cohort study, set up in 1989 and funded by the MRC and Department of Health (DoH).

AIMS

CFAS aims to estimate the prevalence and incidence of cognitive decline and dementia and geographical variation; to determine the natural history of dementia, in particular the rate of progression of cognitive decline, including the distribution of the interval between identification of cognitive impairment and death; to identify factors associated with differing rates of cognitive decline and with the risk of dementia; to determine the contribution of different underlying pathologies to rates of dementia, geographical variation and burden of disability; to evaluate the degree of disability associated with cognitive decline and service needs generated; to set up a brain and blood resource; and to provide a framework to support sub-studies.

METHODOLOGY

The study has five methodologically identical centres (Cambridge, Gwynedd, Newcastle, Nottingham and Oxford) and one

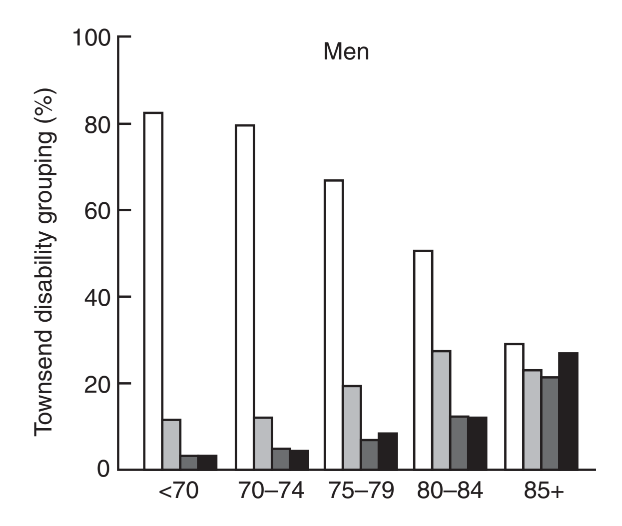
Screening interview:
Sociodemographics
Activities of daily living
Physical health
Smoking, alcohol
Cognitive function
Medication

Assessment interview:
Geriatric mental state (GMS)
allowing AGECAT
CAMCOG, MMSE
Extra items for ICD and DSM

Informant interview*:
History and aetiology schedule (HAS)
Hachinski, Blessed

Selection from screen to assessment

Age (years)	AGECAT O3+	MMSE LE 21	MMSE 22–25	MMSE 26–30	MMSE missing
65–74					
Four centres*	1	1	2/3	1/10	1
Cambridge	1	1	1/4	1/10	1
≥ 75					
Four centres*	1	2/3	1/3	1/13	2/3
Cambridge	1/2	1/2	1/7	1/15	1/2



*Four centres: Gwynedd, Newcastle, Nottingham, Oxford

Figure 1. MRC CFAS: methodology (five identical centres). + Declaration of intent (DoI) to donate brain at post mortem. *Informant interview

centre (Liverpool) with a different design and funded earlier. Each of the five centres obtained a stratified random sample from Family Health Service Authority lists of sufficient individuals aged 65 years and over to achieve at least 2500 interviews (*see* Figure 1 for the study design). The Liverpool study consisted of a sample of 6035 individuals aged 65 years and over, stratified by sex and 5 year age bands. 5222 received a detailed assessment interview, with a selection also receiving the same interview by a clinician 3 months later. This process was repeated at 2 and 4 years. At 7–8 years the cohort was reinterviewed using the five-centre combined screen and assessment interview.

BRAIN DONATION

At all waves of the study, selected participants and their families have been approached with a request to consider donating brain tissue after death. Procedures are in place to collect, process and examine brains from these individuals, which are stored locally. There are currently 347 brains within the Neuropathology study and 209 have been used for a first analysis. There are a further 500 people who have made a declaration of intent to donate brain tissue (DoI) and the continuing mechanism for collection will enable us to reach our target of 450.

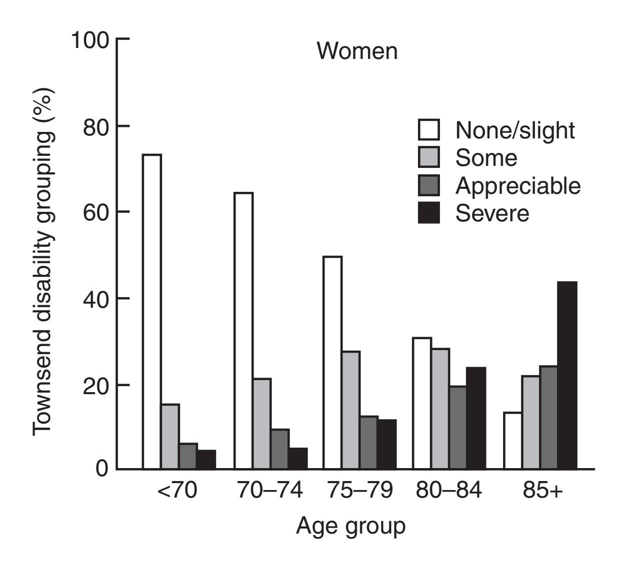


Figure 2. Percentage within Townsend disability grouping by age group and sex. From reference 2, with permission

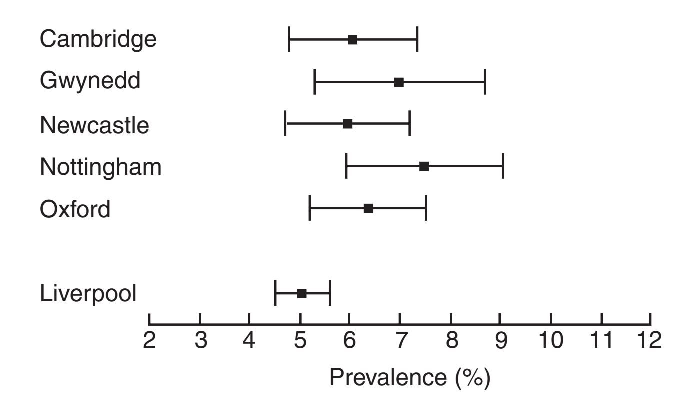

Figure 3. Prevalence estimates with 95% confidence intervals for AGECAT organicity O3+. From reference 3, with permission

Table 1. Estimated numbers of cognitively impaired or disabled elderly people in England and Wales by age group, sex and type of disability

	64–74 years		75–84 years		⩾85 years	
Disability	Men	Women	Men	Women	Men	Women
Physical only	68 000	122 000	82 000	257 000	43 000	232 000
Cognitive only	32 000	29 000	45 000	57 000	20 000	61 000
Combined	14 000	11 000	26 000	57 000	27 000	99 000

From reference 1, with permission.

BLOOD RESOURCE

During wave 2 in Oxford, wave 3 in Cambridge, Gwynedd, Newcastle and Nottingham and wave 4 in Liverpool, a blood sample (or saliva when blood was refused) was requested. There are 1126 blood and 193 saliva samples from the assessed groups in five sites (Cambridge, Liverpool, Gwynedd, Newcastle and Nottingham) and a further 1600 from the full wave 2 population in Oxford.

MORTALITY DATA

The full sample of 24 066 is flagged on the NHS Central Register at the Office for National Statistics (ONS); 11 104 death notifications, with causes coded to ICD-9, have been received. The death information complements and enhances data from interviews, as all eligible for entry into the study, together with those actually interviewed, were flagged. This enables tracking of all individuals from initial sampling to death.

OUTPUT FROM THE STUDY

Figures 2 and 3 and Table 1 provide some results from published papers. A full bibliography may be found on the CFAS website, http://mrc-bsu.cam.ac.uk/cfas. Work in progress includes measures of healthy life expectancy, estimation of incidence rates, medication usage, normative values for CAMCOG and its subscales, cognitive function as a marker for survival, neuropathology analysis and genetic risk for dementia.

The Epidemiology of Alzheimer's Disease: An Update

Lenore J. Launer

Epidemiology, Demography, Biometry Program,
National Institute on Aging, Bethesda, MD, USA

This chapter provides a short overview on methodologic issues related to the design of epidemiologic studies of dementia, and provides an update on the epidemiology of Alzheimer's disease (AD). AD is characterized by a gradual but steady decline in cognitive and occupational function. A clinical diagnosis of AD is based on the course of the dementia and exclusion of other known causes of dementia. A definite diagnosis of AD can only be made post mortem in the presence of neuritic plaques and neurofibrillary tangles[1]. Although these lesions are considered to be pathognomonic for the disease, it is unclear as to whether they are the primary cause of the disease or are the consequence of other more fundamental processes.

METHODOLOGY

Study Design

Research into the frequency and etiology of dementia is based on studies of prevalent cases and incident cases. Prevalent cases are identified in a cross-sectional study. The probability that they are found depends on the likelihood that they developed into a case and survived until the time of the survey. Thus, there is usually over-representation of cases with long duration. Incident cases are newly developed cases identified in a prospective follow-up study of a cohort that is initially dementia-free at baseline. It is preferable to study etiologic factors related to dementia in incident cases, as there is less likelihood that factors related to survival (or severity of the disease) influence the association of the exposure to the disease.

Measurement of Risk Factors

Ascertainment and interpretation of risk factor data is also less subject to bias when collected from incident, compared to prevalent, cases. In incident cases, a risk factor can be measured at baseline before the onset of dementia. In a prevalent case, a proxy needs to be questioned because a demented person can no longer be expected to provide valid or reliable answers. In addition, some biologic markers in prevalent cases may be influenced by the dementia itself[2].

Case Identification

Most cases of dementia do not come to the attention of the health services. This is the result of many factors, including the cases themselves or their caretakers not recognizing the disease[3] and there presently being few treatment alternatives. Likewise, dementia is under-reported as cause of death. Therefore, studies relying on health care systems or records to identify cases probably only capture moderate to severe cases or cases with exceptional presentation. To fully identify the range of case presentation in the population, including mild cases, population-based studies that interview individuals in person are needed.

Diagnostic Guidelines

Strides in standardization of diagnoses used in research studies have been made in the past decade. Currently, the diagnosis of AD is made on the basis of internationally agreed guidelines for dementia (i.e. DSM-IV[4] and ICD-10[5]) and specific criteria for AD. The most widely used criteria for AD are from the NINCDS–ADRDA[6]. Although application of different guidelines for dementia can identify different individual cases[7], reasonable inter- and intra-rater reliability can be achieved[8] if the same guidelines are used.

RISK FACTORS

Much progress has been made in the past decade in testing hypotheses based on case-control studies[9], and also in identifying new hypotheses.

Age and Sex

All epidemiologic studies show an increase in the frequency of dementia with age, with an almost doubling of prevalence and incidence from age 65–85 years[10,11]. Approximately 65% of cases are attributed to AD, although the proportion of AD cases out of the total might depend on ethnic group[12]. Furthermore, as more neuroimaging is used in diagnosis, more cases of dementia associated with cerebrovascular

disease may be identified[13]. The slope of the increase with age depends on the sub-type of dementia. The incidence of dementia and AD increases steeply with age. The absolute incidence and the age-related increase in vascular dementia is lower. Studies differ concerning the sex-specific risk for AD. After 85 years of age a large difference in incidence was found in European studies[14]; the incidence in women increased steadily with age (up to 82/1000 person-years at 90 years and older), but flattened out in men (at 25/1000 person-years at 90 years and older). In contrast, in USA-based cohorts[15,16], the incidence of dementia, or AD, increased in old age with no apparent differences by sex. Sex differences in the risk for AD may be due to differences in biology, cumulative survival, or behaviour and exposures. Further investigations are needed to clarify the contribution of sex to the risk for AD.

Education

The contribution of education to the risk for AD is still controversial. Some argue that an association reflects confounding by socioeconomic factors, or diagnostic bias due to poorer performance on neuropsychological tests by individuals with low education[17]. Others argue that education is a marker for biological capacity that modulates when a person reaches the threshold of clinical dementia[18]. Several studies based on prevalent cases show that low education is associated with an increased risk for AD[19]. Studies based on incident cases are inconsistent, with some showing no relation[20] and others showing a relationship[21] of low education to increased risk for AD. In one study the increased risk associated with AD was confined to women[22].

Head Trauma

Reports on the relation of AD to head trauma with unconsciousness are inconsistent. Most studies are based on prevalent cases, where a proxy has had to be asked about the case's history of head trauma. These studies have either shown no effect[23], an increased risk for AD only in men[24], or only in women with head trauma[25]. In a study based on US war veterans with independently documented history of head trauma during the war, there was a two-fold increased risk for AD[26]. One report suggested that head trauma is a risk factor in the presence of the apolipoprotein E*4 allele[27] but two other studies have failed to confirm this[24,28].

Cardiovascular Risk Factors

One new area that is being investigated is the relation to AD of cardiovascular disease and risk factors. Several direct and indirect mechanisms may explain such associations, including ischemia, hypoxia, hemodynamic factors and neurotransmitter metabolism[29]. Studies have reported an increased risk for AD associated with subclinical measures of atherosclerosis[30] and elevated levels of blood pressure[2]. Indicators of glucose metabolism, including glucose and insulin levels[3] and diabetes[32] have also been associated with an increased risk for AD, although not consistently[33]. In addition, cardiovascular risk factors have also been shown to increase the risk for AD, including smoking[34,35] and diet[36]. Since this is a relatively new area of investigation, confirmation of these findings in other studies is needed.

Steroidal Hormones

Estrogen may be linked to AD through several direct mechanisms related to amyloid processing, neurotransmitter metabolism, cerebral blood flow or through cardioprotective pathways[37]. Epidemiologic studies based on prevalent cases are inconsistent, some show a positive effect[38], others not[39,40]. Prospective studies suggest that estrogen replacement therapy is protective[41–44]. However, these observational studies may be detecting an association of AD to healthy behaviour, as hormone replacement therapy users tend to be healthier[45]. Studies examining estrogen effects in men, as well as clinical trials, are needed to confirm the association of increased estrogen levels to a reduced risk for AD.

NSAIDs

Based on finding remnants of inflammatory processes in neuropathologic material of AD brains, it has been hypothesized that anti-inflammatory medications may reduce the risk for AD[46]. There have been many case-control studies based on prevalent cases[47]. Although some of these studies show no effect, those that do provide estimates of as much as an 80% reduced risk[48]. More recently, several prospective studies have been published, with inconsistent results. Studies with one measure at baseline and subsequent follow-up found no association[49,50], and another showed a non-significant reduced risk among those using NSAIDs for 6 months or more within 10 years prior to the diagnosis of dementia[51]. In the Baltimore Longitudinal Study of Aging, the risk of AD decreased with increasing duration of NSAID use over a 16 year follow-up[52]. As with the estrogen hypothesis, that pertaining to NSAIDs needs to be tested in controlled clinical trials.

Genetics

With time, increasingly more will be known about the genetics of AD. Currently, several specific mutations have been found in familial (early onset) cases of AD, including missense mutations in the β-amyloid precursor protein on chromosome 21[53] and mutations in the presenilin-1 (chromosome 14q)[54] and presenilin-2 (chromosome 1) genes[55]. However, these mutations do not account for the vast majority of cases, which are sporadic and of later onset. To date, apolipoprotein is the only identified polymorphism that has consistently been shown to be associated with a genetic susceptibility to sporadic and late-age onset AD. Specifically, the e*4 allele increases the risk for AD[56]. Genes involved in inflammatory, apoptotic, metabolic, cytoskeletal, and neurotransmission processes are also under investigation[57]. However, their role in modulating the risk for AD needs further elucidation. There are examples where a polymorphism is found to increase the risk for AD in one sample, but the findings cannot be replicated in others (i.e. such as the polymorphism in the gene encoding α2-macroglobulin[58,59]). Identification of genetic factors contributing to AD will not be simple. The majority of cases are probably a pool of heterogeneous conditions. It is not likely that there will be one or two major genes that are identified; rather, the genetic risk for AD will likely be the product of a number of genes that make a small contribution to risk.

SUMMARY

In the past decade many more prospective population-based studies were started and have yielded valuable data. However,

besides age and the apolipoprotein gene, few risk factors have been shown consistently to reduce, or to increase, the risk for AD. With advances in our understanding of the brain and our genetic code, rapid progress should be made in identifying environmental and genetic risk factors and in studying the interaction between the two.

The Lundby Study, 1947–1997

Per Nettelbladt[1], Olle Hagnell[1], Leif Öjesjö[2], Lena Otterbeck[1], Cecilia Mattisson[1], Mats Bogren[1], Erik Hofvendahl[1], Per Toråker[1]

[1]*Lund University Hospital and* [2]*Karolinska Institute, Stockholm, Sweden*

The Lundby Study is a prospective, longitudinal investigation of all kinds of mental disorders in a total population. It started in 1947, when four psychiatrists, Essen-Möller *et al*., interviewed and described all the 2550 inhabitants of a geographically delimited area in southern Sweden. They were interested in finding out how many people were suffering from a mental illness or deviation, and also the way normal and abnormal personality traits were distributed in a normal population. They traced and examined all but 1% of the population. Only four people refused to participate. After 10 years, in 1957, the field investigation was repeated. One psychiatrist alone (Hagnell) re-examined the original population from 1947, irrespective of domicile. For deceased persons, information was collected from hospital case notes and from relatives. Hagnell also examined the 1013 newcomers in Lundby and thus performed a new prevalence study of 2612 people, as well as a 10 year incidence study of the original 2550 subjects. In 1972 Hagnell and Öjesjö made a second follow-up study[1] including the total population of 3563, also this time irrespective of domicile, thus performing a 25 year and a 15 year incidence study. The participation rate was as high as 98% at the two follow-ups.

All the three field examinations were performed in a similar way. One part of the examination was a semi-structured interview, the other part a free conversation. The task of the psychiatrist was to collect the information to the best of his ability, observantly looking for symptoms and signs. In an investigation such as this, the data should ideally be collected by a trained psychiatrist. To facilitate his task, the psychiatrist had a structured form to fill in. Each interview turned out to be different, but the information gathered was noted in a systematic way. Supplementary information was collected from, amongst other sources, official registers, hospital case notes, autopsy reports, social insurance offices, local officials and relatives. This additional information from other sources forms a rich resource and has proved to be particularly valuable when evaluating the dementias of the elderly. All the types of information collected formed the basis for the global evaluation and classification.

The material from the three field studies has enabled us not only to estimate the rates of prevalence, incidence and probability of developing a mental illness, but also to identify possible background factors of, for example, dementia, starting with people who were healthy at one investigation but who had contracted the illness before the next. Trying to identify risk factors is a weighty enterprise in which we are still involved.

In an epidemiological, psychiatric investigation, precise clinical classification tools are hardly applicable. For dementias among the elderly we use two diagnostic groups: senile dementia of the Alzheimer type (SDAT) and vascular dementia (MID), the latter characterized by focal brain symptoms. Of course, other dementias of the elderly exist but they are fairly unusual compared with SDAT and vascular dementia and not very easily recognized in epidemiological investigations.

In order also to be able to include the hereditary aspect, we have mapped out the kinship of every proband down to the sixth generation, and for the original 2550 even down to the seventh generation.

From the Lundby Study, several reports on dementias in the elderly have been published. Figures from the 1972 prevalence study are included in the EURODEM comparative prevalence studies[2,3]. For the 10 year age groups 60, 70 and 80, the prevalence

The Lundby Study is a prospective, longitudinal investigation of all kinds of mental disorders in a total population. It started in 1947, when four psychiatrists, Essen-Möller *et al*., interviewed and described all the 2550 inhabitants of a geographically delimited area in southern Sweden. They were interested in finding out how many people were suffering from a mental illness or deviation, and also the way normal and abnormal personality traits were distributed in a normal population. They traced and examined all but 1% of the population. Only four people refused to participate. After 10 years, in 1957, the field investigation was repeated. One psychiatrist alone (Hagnell) re-examined the original population from 1947, irrespective of domicile. For deceased persons, information was collected from hospital case notes and from relatives. Hagnell also examined the 1013 newcomers in Lundby and thus performed a new prevalence study of 2612 people, as well as a 10 year incidence study of the original 2550 subjects. In 1972 Hagnell and Öjesjö made a second follow-up study[1] including the total population of 3563, also this time irrespective of domicile, thus performing a 25 year and a 15 year incidence study. The participation rate was as high as 98% at the two follow-ups.

All the three field examinations were performed in a similar way. One part of the examination was a semi-structured interview, the other part a free conversation. The task of the psychiatrist was to collect the information to the best of his ability, observantly looking for symptoms and signs. In an investigation such as this, the data should ideally be collected by a trained psychiatrist. To facilitate his task, the psychiatrist had a structured form to fill in. Each interview turned out to be different, but the information gathered was noted in a systematic way. Supplementary information was collected from, amongst other sources, official registers, hospital case notes, autopsy reports, social insurance offices, local officials and relatives. This additional information from other sources forms a rich resource and has proved to be particularly valuable when evaluating the dementias of the elderly. All the types of information collected formed the basis for the global evaluation and classification.

The material from the three field studies has enabled us not only to estimate the rates of prevalence, incidence and probability of developing a mental illness, but also to identify possible background factors of, for example, dementia, starting with people who were healthy at one investigation but who had contracted the illness before the next. Trying to identify risk factors is a weighty enterprise in which we are still involved.

In an epidemiological, psychiatric investigation, precise clinical classification tools are hardly applicable. For dementias among the elderly we use two diagnostic groups: senile dementia of the Alzheimer type (SDAT) and vascular dementia (MID), the latter characterized by focal brain symptoms. Of course, other dementias of the elderly exist but they are fairly unusual compared with SDAT and vascular dementia and not very easily recognized in epidemiological investigations.

In order also to be able to include the hereditary aspect, we have mapped out the kinship of every proband down to the sixth generation, and for the original 2550 even down to the seventh generation.

From the Lundby Study, several reports on dementias in the elderly have been published. Figures from the 1972 prevalence study are included in the EURODEM comparative prevalence studies[2,3]. For the 10 year age groups 60, 70 and 80, the prevalence

rates of SDAT in the Lundby Study were, for both sexes taken together, 0.3%, 2.5%, and 10.9%, respectively, and for vascular dementia 0.8%, 3.5%, and 6.3%.

The rates of incidence and cumulative probability of contracting SDAT or vascular dementia were also published[4,5]. The cumulative lifetime probability of contracting SDAT was reported to be 25.5% in men and 31.9% in women. If only the most severely impaired cases are counted, the figures are 15.0% and 22.2%, respectively. For vascular dementia the figures are 29.8% in men and 25.1% in women, for severe cases 16.6% and 15.2%, respectively.

Attempts have been made at finding background factors of a precipitating or protective nature in SDAT and vascular dementia in the Lundby Study. Two articles on this topic have been written[6,7].

On 1 July 1997 the Lundby Study[1,8,9] celebrated its 50th anniversary by launching a new re-examination of its population, now aged 40+. This fourth wave of the Lundby Study gives an opportunity to study the occurrence of mental disorders and, as the population has grown 25 years older since 1972, especially mental disorders in an ageing population.

Between 1 July 1947 and 1 July 1972, 736 probands had died, and between 1 July 1972 and 1 July 1997, 1028 probands had died. On 1 July 1997, in all, 1764 probands were deceased. Thus, the number of living probands on 1 July 1997 was 1799 (3563–1764). This field investigation is now completed and the participation rate is still high (approximately 90%).

In the 1997 Lundby Study, modern diagnostic systems, such as DSM-IV[10] and ICD-10[11], are used, together with the old diagnostic Lundby classifications. When the interview is finished, the proband is given a set of self-rating questionnaires. The proband is asked to complete them and to return them to the Lundby Study. The self-rating questionnaires are: the Interview Schedule for Social Interaction about social network[12], the Nottingham Health Profile about quality of life[13], the Sense of Coherence Scale (about salutogenesis)[14], and the Hopkins Symptom Check List, a mental symptom check list[15]. Also, this time supplementary information will be collected.

Focusing on the mental health/illness and its consequences as the present prospective, longitudinal study can shed light on the incidence and course of mental disorders in the middle-aged and elderly and estimate the importance of health care and treatment. By revisiting and examining the Lundby population a fourth time, the Lundby database will be updated. No comparable study has been progressing for such a long period of time.

Nutritional Factors in Dementia

D. N. Anderson[1] and M. T. Abou-Saleh[2]

[1]*Mossley Hill Hospital, Liverpool, and* [2]*St George's Hospital Medical School, London, UK*

The prevalence of nutritional disorders among the elderly is substantial, particularly among the elderly mentally ill (*see* Chapter 138a). Those with dementing disorders are at special risk. Dementia caused by a single nutrient deficiency is rare in the UK and USA and malnourishment will normally be the result of a dementia and deranged eating patterns, rather than its cause. The elderly in hospital or residential care are more likely to be malnourished than those living in the community[1,2].

Reduced plasma and blood levels of folate[3–6], vitamin B_{12}[3], vitamin C[2,5,7–10], and vitamin E[8–10] in particular, have been reported in association with dementia and cognitive impairment.

Goodwin *et al.*[11] reported a direct relationship between water-soluble vitamins and cognitive function in healthy subjects. Those with the lowest levels of plasma folate and vitamin B_{12} scored significantly worse on the Halstead–Reitan categories test and the Wechsler memory test. As part of the Basle Longitudinal Project on Ageing, involving urban-dwelling healthy elderly people, Perrig *et al.*[12] found that β-carotene and vitamin C levels were independently correlated with memory function after controlling for compounding variables such as age, education and gender. High intake of monounsaturated fatty acids was found to be associated with better memory function in 300 people aged 65–84 years[13]. Unsaturated fatty acids appear important for maintaining the development and integrity of neuronal function.

Botez *et al.*[14] having found evidence of organic brain damage on psychometric testing in folate deficient subjects, reported improvement following 12 months' supplementation. Of five patients who underwent radionucleotide cysternography, three showed improvement of cerebral atrophy. Supplementation with vitamin E has been associated with slower development of the pathology of Alzheimer's disease[15].

It is not easy to establish, from studies of this sort, whether nutritional deficiency is a cause or effect of cognitive impairment. Supplementation studies suggest that certain additional nutrients may influence cognitive performance and, whether causative or not, nutrient deficiency may increase cognitive decline. If aetiologically significant, then the relevance of many of these findings may lie in the relationship with the oxidative stress hypothesis of Alzheimer's disease and the significance of oxidative stress for the development of ischaemic vascular disease. There is increasing evidence that reactive oxidizing species contribute to the neuronal damage and formation of the amyloid plaques seen in Alzheimer's disease[16,17]. Antioxidants could be important for preventing this damage and antioxidant constituents of diet, such as vitamins E and C and β-carotene may be of particular importance. Vitamin C is actively concentrated in the brain[18] and is considered to be the most effective antioxidant in human plasma[19].

Impaired antioxidant status[20] and low plasma vitamin C levels[21] have been suggested as risk factors for coronary artery disease and, therefore, may be relevant to dementia of vascular origin. Similar associations have been reported with vitamin B_6 and folate consumption[22]. Preliminary suggestions that vitamin E may reduce the risk of stroke has obvious implications for the development of vascular dementia.

The causative role of thiamine deficiency for the Wernicke–Korsakoff syndrome is established and it seems that some alcoholic dementias may result from Wernicke–Korsakoff lesions[23]. Other B vitamins are capable of producing cognitive impairment and dementia[24] but are only likely to be significant causes in industrially underdeveloped countries.

Assessment of nutritional status should be part of the general management of dementing patients and nutritional deficiency corrected whenever possible. The cause of undernutrition is multifactorial and various interventions may help to improve a patient's nutritional state[25] (*see* Chapter 138a). For a few patients this may lead to gratifying improvements of cognitive performance, but all are likely to benefit by a reduction of morbid risk and improvements in general health. It is likely that a clearer understanding of the relationship between dietary constituents and dementia will contribute to methods of prevention and treatment of this condition.

The Genetics of Alzheimer's Disease

Brenda L. Plassman[1] and John C. S. Breitner[2]

[1]*Duke University Medical Center, Durham, NC, and* [2]*Johns Hopkins University, Baltimore, MD, USA*

Knowledge of the genetics of Alzheimer's disease (AD) has advanced in recent years. Like many other diseases of late life, AD exhibits a complex pattern of inheritance. It is difficult to localize genes that cause such diseases, however, partly because only recent generations are available to be genotyped and phenotyped. This chapter will provide a general overview of the current state of knowledge in the genetics of AD and related dementias, and suggest approaches to interpretation of future findings in this area.

FAMILY AND TWIN STUDIES

The striking early evidence for genetic causes of AD was based on a few multigenerational kindreds with many individuals with the disease (for review, *see* ref. 1). Most of these families had onset of disease before the age of 65, and were thus arbitrarily classified as having "early onset". These multigenerational kindreds with so-called familial AD probably represent no more than 1–2% of all AD cases, but their existence strongly suggested that genes were important in at least some cases of AD.

Other early work supporting a genetic etiology of AD was based on the presence of a positive family history of the disease in clinical and population-based AD samples. Most of these studies showed an increased risk of AD in first-degree relatives, ranging from 25% to 50%, as compared with 10% or less for non-demented controls[2]. This finding suggested an up to five-fold increase in risk of AD among relatives of individuals with the disease.

The early family studies focused on families at greater risk of developing AD. Recently, however, some researchers have taken another approach to the problem by investigating families who appear to have a *lower* risk of AD[3]. They have shown that the first-degree relatives of individuals who reached the age of 90 and were not demented had a reduced liability to AD from age 60 on, as compared with the families of younger non-demented individuals. The message here is that genes may either promote or reduce the risk of AD.

Twin studies have provided other evidence for genetic causes of AD. Members of identical (monozygotic) twin pairs share 100% of their genome, while fraternal (dizygotic) twin pairs share 50% of their genes on average. The twin design assumes that the degree of similarity in the early life environments of identical and fraternal twin pairs are the same. Based on this so-called "equal environments assumption", the twin design compares concordance rates for disease in identical (monozygotic) twin pairs with that in fraternal (dizygotic) pairs. Higher concordance in identical pairs, then, implies genetic influences. The magnitude of such influences can be estimated in complex models that simultaneously assess the proportion of disease liability attributable to shared or unique environmental causes, as well as stochastic variation[4].

Like the early family studies, twin studies of AD have generally implied genetic causation without identifying particular genes or loci. The heritability of AD (proportion of disease liability attributable to genes) has been estimated from ongoing studies of AD in three population-based twin registries: (a) the NAS–NRC Twin Registry in the USA[5]; (b) the Swedish Twin Registry[6]; and (c) the Norwegian Twin Registry[7]. Based on tetrachoric correlation analyses, current estimates of heritability for AD in these studies range from 0.33 to 0.74[5–7]. We suggest that the wide range of these estimates of heritability may reflect the differences in the age distribution of twins in the three registries. We speculate that the lowest heritability estimate (0.33) from our work may underestimate the true heritability of AD because of the atypically young age (mean onset age = 67 years) of AD cases in the NAS–NRC sample. Others have shown that the risk of developing AD, for a relative of a proband with AD, increases with age at least until the mid-80s[8]. Consistent with this, we have found that the estimates of heritability in the NAS–NRC Registry have gradually increased over the past few years. As the Registry approaches the typical age of risk for AD of the late 70s, 80s and even beyond, we anticipate that heritability in the NAS–NRC sample will approximate that of the other two studies and the consensus estimate of heritability will likely be between 0.5 and 0.65.

MOLECULAR GENETICS

Autosomal genes with dominant expression

Motivated by the findings from family and twin studies, molecular genetic techniques have now identified mutations at three genetic loci that are associated primarily with early onset AD. Initial interest in the molecular genetics of AD focused on chromosome 21, because aging Down's syndrome patients (trisomy 21) often exhibit the brain pathology seen in AD patients[9,10]. The first identified AD mutation was found in the β-amyloid precursor protein (*APP*) located on chromosome 21[11]. This mutation substitutes isoleucine for valine at codon 717 in exon 17[11]. Since the first report of this missense mutation, a number of other *APP* mutations have been identified (for review, *see* ref. 12). But, in total, the *APP* mutations appear to account for the disease in less than 20 families worldwide.

The second genetic locus to show linkage to AD was found on chromosome 14[13,14] and was termed presenilin-1 (*PS-1*)[15]. Over 40 mutations in the *PS-1* locus have now been reported in at least 82 families world-wide[16]. Like the *APP* mutations, *PS-1* mutations

appear to act as autosomal (i.e. not sex-linked) dominant traits with nearly complete penetrance[16]. Early reports suggested that chromosome 14 mutations may account for the majority of early-onset familial AD cases[17,18]. More recent estimates from population-based samples[16,19] have produced conflicting estimates of the proportion of early-onset cases attributable to *PS-1* mutations, with some[16] suggesting that *PS-1* mutations account for less than 20% of such cases (*see* p. 217 for more discussion of presenilins).

A third autosomal dominant locus for AD has been localized to chromosome 1 and termed presenilin 2 (*PS-2*)[20,21]. To date, *PS-2* mutations have been identified in only a few families of different ethnicity. In fact, in a population-based sample of early-onset AD cases, it was estimated that *PS-2* mutations account for less than 1% of the cases[16]. The *PS-2* mutations usually provoke onset of AD symptoms before age 65, but later onsets occasionally occur. The variability in onset age for the *PS-1* and *PS-2* mutations suggests the complexity of these otherwise Mendelian traits.

Identification of AD mutations on chromosomes 21, 14 and 1 has led to major advances in understanding the etiology of this disease. It is important to note, however, that these mutations probably account in total for less than 2% of all AD cases[22]. Importantly, it appears that they do not account even for the majority of so-called autosomal dominant familial AD[16]. Thus, there are almost certainly other major genes remaining to be identified in early-onset AD. A separate and, from a public health perspective, far more compelling issue is the search for other genetic influences in common, late-onset AD.

Apolipoprotein E

In the search for other so-called AD genes, Pericak-Vance and colleagues[23] reported linkage of disease to a locus on chromosome 19 in pedigrees with late-onset AD. Searching through the candidate genes of the implicated region on chromosome 19, Strittmatter *et al.*[24] found that the apolipoprotein E gene (*APOE*), which encodes the lipid transporter apolipoprotein E (apoE), is located in the same region that showed linkage to familial late onset AD. Their initial studies showed an increase in amyloid deposition in elderly individuals with the ϵ4 allele at *APOE*[24,25], and an increased frequency of this allele in both familial and sporadic AD cases[25–29]. Subsequent studies showed that, as the number of ϵ4 alleles increases from 0 to 2, the age of onset of AD decreases[30]. These findings have now been confirmed in over 100 studies, including some that extend the findings to early onset AD (for review, *see* ref. 31). A recent meta-analysis of data on over 14 000 subjects from 40 research teams synthesized the findings on *APOE* through 1997[32]. That study confirmed the basic findings noted above and also replicated some findings that previously had been suggested by select studies. These findings were that the *APOE* ϵ2 allele may be associated with lower risk of AD, and that risk associated with the ϵ4 allele appears to vary by age, sex, and ethnicity. The association between AD and *APOE* ϵ4 is complex, and it is not clear why some individuals with the ϵ4 allele develop the disease while others do not. But, whatever its precise role, ϵ4 is an important player in the genetics of AD, as various groups have now estimated that *APOE* accounts for 57–70% of the genetic contribution of AD[33–35]. Further discussion of the role of *APOE* on the risk of AD is provided on pp. 218–19.

Other Putative Genes

There are many pedigrees that show intense familial aggregation of either early- or late-onset AD but have no identified mutation and no *APOE* ϵ4 allele. It seems likely, therefore, that one or more genes predisposing to AD remain to be discovered. The pursuit of these other genes has produced numerous reports of associations between specific genes and AD, but none of these has been consistently replicated. Chromosome 12 has been the focal point of much of this work, since a genomic screen showed a region on this chromosome may be associated with increased susceptibility to AD in individuals without an *APOE* ϵ4 allele[36]. Further analyses by this group has suggested that a region on chromosome 12 near the one of original interest may be associated with increased risk of the Lewy body variant of AD[37]. Other groups have now demonstrated linkage to regions near the initially implicated chromosome 12 locus, although one such study suggested that the strongest such association was in individuals *with* an ϵ4 allele[38], while the other showed the strongest association in those *without* an ϵ4 allele[39].

Two of the several candidate genes in the region under scrutiny on chromosome 12 have now been shown to be positively associated with AD in at least some studies. The first is the gene for the major apoE receptor in the brain, the low-density lipoprotein receptor-related protein (LRP) that is selectively found in neurons and reactive astrocytes[40]. This gene, *LRP*, has also been shown to mediate the endocytosis and degradation of Aβ[41]. It has two alleles, called C and T. The homozygous C genotype appears to be associated with increased risk of AD, earlier onset of AD, and significantly more neuritic plaques at post mortem, as compared to individuals with at least one T allele[42]. Several groups have confirmed these results[43–46], but at least two have not[47,48].

The other candidate locus encodes α-2 macroglobulin (*A2M*) and is located just outside the area on chromosome 12 for which others have reported linkage[36]. Previous work[41] showed that *A2M* is a major LRP ligand and is a serum pan-protease inhibitor that mediates the clearance and degradation of Aβ, the major component of brain amyloid. At least three different *A2M* polymorphisms have been implicated so far[49–51]. One of these studies reported that, in a very elderly Finnish cohort, the association with the *A2M* polymorphism was only evident in neuropathologically diagnosed AD cases, but not in the clinically diagnosed AD cases. This particular polymorphism was also associated with an increase in the neocortical β-amyloid protein load[51]. Unfortunately, a number of other studies have not confirmed these associations between *A2M* and AD in several large samples[52–56]. Together, these findings suggest that if *A2M* is associated with AD, its effect may be limited to subgroups of susceptible individuals and that different polymorphisms may be influential in each of these subgroups.

With so many purported loci and mutations associated with AD, one may wonder about a common thread in the pathogenesis of AD. The pathogenic mechanisms of the *APP*, *PS-1* and *PS-2* mutations are not completely understood, but each appears to be associated with increased production of the long form of Aβ (Aβ-42), relative to the production of the shorter forms (mostly Aβ-40) of Aβ[57]. Aβ-42 seems to be a particularly pathogenic form of Aβ in AD. Both *LRP* and *A2M* are involved in the degradation of Aβ. It has been suggested that these links to Aβ may be the underlying common pathogenic event leading to AD for these genes[58].

There are reports of numerous other genes throughout the genome contributing to AD, but none of these findings has been consistently confirmed. A partial list of the contending genes includes: α_1 antichymotrypsin (*ACT*), a gene on chromosome 14[59–67]; the K variant of butyrylcholinesterase (*BCHE-K*) on chromosome 3[68–72]; bleomycin hydrolase (*BH*) on chromosome 17[73] (cf. ref 74); the non-amyloid component precursor gene (*NACP*/α-synuclein) on chromosome 4[75] (cf. ref 76); the human leukocyte antigen (*HLA*) genes on chromosome 6[77,78]; the *FE65* gene on chromosome 11[79]; the dihydrolipoyl succinyltransferase (*DLST*) gene on chromosome 14[80,81]; the

interleukin-1 (IL-1) on chromosome 2[82,83]; and the mitochondrial cytochrome *c*-oxidase (CO) genes *CO1* and *CO2*[84]. To make matters more complicated, many of the above-named genes have been shown to interact in varying degrees with *APOE* or other genes to alter risk of AD[85].

There are several possible reasons for the contradictory results of the association studies noted above. Other authors have proposed that they may reflect: (a) different etiologies in different ethnic populations; (b) lack of adjustment for multiple comparisons (type I statistical error, resulting from simultaneous screening of many different candidate loci); (c) linkage disequilibrium in some (or all) populations between the tested polymorphism and the functional polymorphism; or (d) inability to detect an effect due to limited statistical power or weak genetic effects[39,86]. Association studies are also more difficult to interpret when one does not know such characteristics as the mode of inheritance, age-dependent expression characteristics, interaction with other loci, misdiagnosis rate, and disease allele frequency. Finally, the inconsistent findings may reflect interactions with non-genetic factors. There is convincing evidence implicating *non-genetic* factors in the etiology of AD, either alone or in interaction with specific genes[87,88]. The most compelling indications of this effect are the numerous reports of monozygotic twin pairs who, although genetically identical, remain discordant for AD for 10 or more years[5,89–91].

Collectively, the three twin studies previously described suggest that non-genetic influences account for at least 25% of the variance in AD susceptibility. Studies of these "environmental factors" have suggested that both potentiating and protective influences may operate by primarily altering the timing of onset[92–94]. Similar to the recent reports of genetic associations, however, few non-genetic risk factors have been consistently confirmed. For further discussion on the genetic epidemiology of AD, see pages 219–21.

CONCLUSION

Given the number of AD genes already identified and the proportion of cases attributed to each of these genes, we can reasonably predict that there will be more than one other new gene implicated in AD. Based on what we know about the complexity of the relationship of AD and the genes identified to date, it is likely that any newly identified genes will also interact with other genes and with non-genetic factors. Also, the effect of any one gene may be influenced by the age, sex, and ethnicity of the at-risk individual. Therefore, any newly identified genes will need extensive evaluation and confirmation in various subpopulations before they are added to the list of AD genes.

Until the search for genetic and non-genetic causes of AD is complete, there is no way of identifying those individuals who will definitely develop AD. However, the discovery of new AD genes may have benefits beyond just identifying those at increased genetic risk for the disease. At least two lines of evidence suggest that there may be a common underlying pathological mechanism regardless of the genes involved. First, multiple predisposing genes appear to produce the same AD phenotype. Second, all of the AD genes identified to date, and some of the other candidate genes under examination, have some link to the metabolism of $A\beta$, a neuropathological marker of the disease. Understanding this common feature may lead to evidence of a common destructive metabolic process (i.e. final common pathway) and may be the key to identifying susceptible individuals *before* they develop the full syndrome of AD, or even preventing the disease. Because clinically normal individuals with at least one *APOE* ϵ4 allele have "AD neuropathology" as early as the fourth decade of life[95], one might postulate that other "AD genes" may also begin their destructive process early in life. If one could find the common pathological mechanism for the disease, then regardless of the genetic or non-genetic factors that initiate the process, treatment could be implemented to delay or prevent progression of the disease. The underlying premise is that it may be more feasible to identify a "marker for the disease process" and develop a test to measure a single marker present fairly early in life, rather than try to develop an algorithm to predict AD that includes all possible variations of genetic and non-genetic risk factors for disease.

The Role of Presenilins in Alzheimer's Disease

David M. A. Mann

University of Manchester, UK

It is now 5 years since the presenilins and their association with Alzheimer's disease (AD) was discovered, although homologues, *sel-12* and *spe-4*, in the animal kingdom had been known about earlier. By 1994, the AD3 locus for early onset familial AD had been mapped to chromosome 14q 24.3, where causative mutations in a gene encoding a novel protein, initially called S182 but later presenilin-1 (PS-1), were identified[1]. Over 60 different PS-1 mutations have now been found. A homologous gene on chromosome 1, presenilin-2 (PS-2), is the AD4 locus; here three AD-causing mutations have been found[1]. Both presenilin proteins span the membrane six to eight times, with C- and N-termini facing intracellularly and a large cytosolic loop region occurring between transmembrane helices 6 and 7.

Recent research has focused on understanding how changes in presenilin protein structure might facilitate disease[2]. Cell lines and transgenic mice bearing PS-1 (and PS-2) mutations produce more amyloid β protein (Aβ), particularly the highly fibrillogenic Aβ_{42}, than wild-type PS-1. Humans with PS-1 mutations produce more Aβ_{42} in cell culture, plasma levels are elevated and brain deposition is high. Catabolism of APP along pathways favouring production of Aβ is therefore enhanced when PS-1 mutations are present, driving the pathological cascade that leads to clinical dementia[2].

PS-1 protein occurs within the perikaryon and dendrites of nerve cells, mostly within the early Golgi apparatus and smooth endoplasmic reticulum. No difference in distribution or amount of

The Role of Presenilins in Alzheimer's Disease

David M. A. Mann
University of Manchester, UK

It is now 5 years since the presenilins and their association with Alzheimer's disease (AD) was discovered, although homologues, *sel-12* and *spe-4*, in the animal kingdom had been known about earlier. By 1994, the AD3 locus for early onset familial AD had been mapped to chromosome 14q 24.3, where causative mutations in a gene encoding a novel protein, initially called S182 but later presenilin-1 (PS-1), were identified[1]. Over 60 different PS-1 mutations have now been found. A homologous gene on chromosome 1, presenilin-2 (PS-2), is the AD4 locus; here three AD-causing mutations have been found[1]. Both presenilin proteins span the membrane six to eight times, with C- and N-termini facing intracellularly and a large cytosolic loop region occurring between transmembrane helices 6 and 7.

Recent research has focused on understanding how changes in presenilin protein structure might facilitate disease[2]. Cell lines and transgenic mice bearing PS-1 (and PS-2) mutations produce more amyloid β protein (Aβ), particularly the highly fibrillogenic $A\beta_{42}$, than wild-type PS-1. Humans with PS-1 mutations produce more $A\beta_{42}$ in cell culture, plasma levels are elevated and brain deposition is high. Catabolism of APP along pathways favouring production of Aβ is therefore enhanced when PS-1 mutations are present, driving the pathological cascade that leads to clinical dementia[2].

PS-1 protein occurs within the perikaryon and dendrites of nerve cells, mostly within the early Golgi apparatus and smooth endoplasmic reticulum. No difference in distribution or amount of

PS-1 protein or its message are seen in PS-1 AD. The holoprotein is processed into 17 kDa, C-terminal (CTF) and 27–28 kDa, N-terminal (NTF) fragments which accumulate in 1:1 stoichiometry, in a highly regulated and saturable manner. Cleavage occurs within the hydrophilic loop, around amino acid 298[2]. PS-1 (2) mutations alter neither the site nor the manner of endoproteolysis, although the cleaved products may accumulate through increased stability.

Amyloid precursor protein (APP) trafficking from Golgi to endosome and plasma membrane—the principal sites of Aβ production—is not affected by PS-1 mutations. PS-1 knockout mice show normal α- and β-secretase activity, though Aβ production is decreased with accumulation of the C-terminal stub of APP. PS-1 therefore might regulate γ-secretase, as part of the γ-secretase complex, with mutant PS-1 fragments enhancing this activity[3,4].

CTF and NTF of PS-1 form a stable complex containing GSK-3β and β-catenin[5]. The cellular trafficking, stability and turnover of β-catenin is altered by PS-1 mutations[3] and these might interfere with the binding of GSK-3β to tau, possibly promoting hyperphosphorylation and neurofibrillary tangle formation.

PS-1, therefore, probably regulates the sorting and processing of integral membrane proteins, including APP. PS-1 mutations may alter protein topology so as to favour APP catabolism along routes which, by increasing production and tissue deposition of Aβ, facilitate the pathological cascade. Other putative roles for presenilins could include signal transduction, involving *Notch* and Wnt pathways, during development or apoptosis[4]. Whether these functions are disturbed by PS-1 mutations, with repercussions for the pathogenesis of AD, is unknown.

Apolipoprotein-E (APO-E)

Dan G. Blazer

Duke University Medical Center, Durham, NC, USA

Strittmatter *et al*.[1] found that the gene apolipoprotein-E (APO-E) for the lipid transporter apolipolipoprotein-E is located on chromosome 19 in a region that was demonstrated to have strong linkage to familial late-onset Alzheimer's disease (AD). There are three common alleles formed at the polymorphic APO-E locus, E2, E3 and E4. Each individual inherits one allele from each parent; thus a person may have an APO-E genotype of E4/E4, E4/E3, E3/E3, and so forth[2]. The E3 allele is the most common and represents approximately 78% of all alleles in European and American White populations. The E4 allele frequency is approximately 15–16% and the E2 frequency approximately 7%. The risk for AD is increased and the average age of onset is decreased with increasing numbers of APO-E E4 alleles. In addition to AD, the E4 allele has been shown to be associated with cardiovascular disease, renal disease, stroke, decreased ability to recover from physiologic challenges such as amnesia and an increase in all-cause mortality. Several case-control and incidence studies of late-onset AD have shown E4 allele frequency to be more frequent in cases; 30–50% in both sporadic and familial AD (FAD), compared to the 15% in the general population. The odds ratio for E4 allele heterozygotes developing AD are approximately 2–5, whereas the odds ratios for E4 homozygotes are 5–18. The E2 allele may actually retard the development of AD.

Other studies of AD and APOE in different ethnic groups report similar associations between the E4 allele and AD. Nevertheless, the frequency of the E4 allele among African-Americans appears to be higher than in Whites, yet the frequency of AD does not appear to be greater (thus suggesting less association, perhaps, in African-Americans compared to Whites).

Despite the association of AD and the APOE-4 allele, most persons who experience AD do not express the E4 allele. In addition, there have been reports of individuals homozygous for E4 in very late life who nevertheless remain cognitively intact. The E4 allele is therefore neither necessary nor sufficient to cause AD. For this reason, the E4 allele has been considered a susceptibility gene. This represents a change in perspective from the typical approach to genetic expression for an autosomal dominant or autosomal recessive.

Most genetic determinants of health do not derive from a one gene–one disease paradigm, but rather a paradigm in which the phenotypic expression of the genome is best conceived quantitatively. A single polymorphism at a specific locus can lead to multiple adverse outcomes, outcomes which can be investigated as changes over time as well as the onset of a specific disease at a specific point in time. In other words, these are susceptibility polymorphisms that are universally distributed in the population, rather than mutations that are uncommon and family-specific. A single allele may be sufficient to cause a specific disease, yet everyone with that allele has a measurable age-dependent risk for that disease. These susceptibility polymorphisms are therefore subject to investigation in the way epidemiologists conceive environmental stressors (such as stressful life events) or health-related behaviors (such as smoking), that is, as risk factors for disease onset and change. To date, however, few such susceptibility polymorphisms have been identified. Studies of these polymorphisms have focused almost exclusively upon the association of an allele with a specific disease or specific adverse outcome, such as mortality. Yet these polymorphisms may increase the risk

Apolipoprotein-E (APO-E)

Dan G. Blazer
Duke University Medical Center, Durham, NC, USA

Strittmatter *et al*.[1] found that the gene apolipoprotein-E (APO-E) for the lipid transporter apolipolipoprotein-E is located on chromosome 19 in a region that was demonstrated to have strong linkage to familial late-onset Alzheimer's disease (AD). There are three common alleles formed at the polymorphic APO-E locus, E2, E3 and E4. Each individual inherits one allele from each parent; thus a person may have an APO-E genotype of E4/E4, E4/E3, E3/E3, and so forth[2]. The E3 allele is the most common and represents approximately 78% of all alleles in European and American White populations. The E4 allele frequency is approximately 15–16% and the E2 frequency approximately 7%. The risk for AD is increased and the average age of onset is decreased with increasing numbers of APO-E E4 alleles. In addition to AD, the E4 allele has been shown to be associated with cardiovascular disease, renal disease, stroke, decreased ability to recover from physiologic challenges such as amnesia and an increase in all-cause mortality. Several case-control and incidence studies of late-onset AD have shown E4 allele frequency to be more frequent in cases; 30–50% in both sporadic and familial AD (FAD), compared to the 15% in the general population. The odds ratio for E4 allele heterozygotes developing AD are approximately 2–5, whereas the odds ratios for E4 homozygotes are 5–18. The E2 allele may actually retard the development of AD.

Other studies of AD and APOE in different ethnic groups report similar associations between the E4 allele and AD. Nevertheless, the frequency of the E4 allele among African-Americans appears to be higher than in Whites, yet the frequency of AD does not appear to be greater (thus suggesting less association, perhaps, in African-Americans compared to Whites).

Despite the association of AD and the APOE-4 allele, most persons who experience AD do not express the E4 allele. In addition, there have been reports of individuals homozygous for E4 in very late life who nevertheless remain cognitively intact. The E4 allele is therefore neither necessary nor sufficient to cause AD. For this reason, the E4 allele has been considered a susceptibility gene. This represents a change in perspective from the typical approach to genetic expression for an autosomal dominant or autosomal recessive.

Most genetic determinants of health do not derive from a one gene–one disease paradigm, but rather a paradigm in which the phenotypic expression of the genome is best conceived quantitatively. A single polymorphism at a specific locus can lead to multiple adverse outcomes, outcomes which can be investigated as changes over time as well as the onset of a specific disease at a specific point in time. In other words, these are susceptibility polymorphisms that are universally distributed in the population, rather than mutations that are uncommon and family-specific. A single allele may be sufficient to cause a specific disease, yet everyone with that allele has a measurable age-dependent risk for that disease. These susceptibility polymorphisms are therefore subject to investigation in the way epidemiologists conceive environmental stressors (such as stressful life events) or health-related behaviors (such as smoking), that is, as risk factors for disease onset and change. To date, however, few such susceptibility polymorphisms have been identified. Studies of these polymorphisms have focused almost exclusively upon the association of an allele with a specific disease or specific adverse outcome, such as mortality. Yet these polymorphisms may increase the risk

for multiple diseases, and therefore for generalized morbidity, and increased the risk of mortality from multiple causes. This translates into increased burden on the health care delivery system and higher costs.

Apolipoprotein E is a major serum lipoprotein involved in cholesterol metabolism. Lipoproteins derived from E4 are cleared more efficiently from the blood than those derived from E3 and E2. Apolipoprotein E does not cross the blood–brain barrier but is synthesized in the brain by astrocytes. In the brain, APOE is thought to be involved in the mobilization and redistribution of cholesterol and phospholipid during membrane remodeling associated with the plasticity of synapses[3].

The biological basis for the association between the E4 allele and AD is unclear, however. APOE is found in senile plaques and fibrillary tangles and binds to Aβ in the cerebrospinal fluid. *In vitro* studies have indicated that APOE isoforms may differentially affect deposition of Aβ. Binding studies suggest that APOE isoforms have different affinities for Aβ. However, these results are controversial because different studies suggest different isoforms have the highest affinity for Aβ. The APOE isoforms have been shown to promote Aβ fibral formation *in vitro*. Other studies, however, show that E3 but not E4 binds to tau, preventing aggregation of tau and neurofibrillary tangle formation. Neurite extension and branching is more extensive in E3-treated cells compared with E4-treated cells. APOE E4 has also been shown to have increased antioxidant activity compared with E3[3].

Although there is a consensus that APOE E4 is strongly associated with AD, this does not mean that tests for the genotype (which are comercially available) should be used for diagnostic testing. A consensus working group has recommended that, at the present time, APOE genotyping should not be used for predictive testings. APOE genotype alone does not provide sufficient sensitivity or specificity to allow genotyping to be used as a diagnostic test. Because AD develops in the absence of E4 and because many patients with APOE E4 seem to escape the disease, genotyping is also not recommended for use as a predictive genetic test[4].

Down's Syndrome and Alzheimer's Disease: Update

David W. K. Kay and Brian Moore

University of Newcastle upon Tyne, UK

One of the unresolved questions for the dementia of Down's syndrome (DS) as a model for Alzheimer's disease (AD) is the long interval, often up to 20 years, that separates the appearance of the AD pathology in the brains of individuals dying after the age of 35 from the clinical manifestations of dementia.

EPIDEMIOLOGY OF DEMENTIA

Study of decline and dementia is important for service as well as theoretical reasons. The life expectancy of a 1 year-old DS child with mild/moderate handicap is now 55 years[2]. However, the wide variation in premorbid abilities and the presence of physical, particularly sensory impairments[1] often makes the diagnosis of dementia difficult. With ICD-10 criteria as standard, the Dementia Questionnaire for Persons with Mental Retardation[3] and the Dementia Scale for Down Syndrome[4] both perform well, but the Mini-Mental State Examination is too difficult[5]. Both caregiver information and longitudinal monitoring of cognitive performance are desirable[6]. Cortical atrophy may be demonstrated by brain imaging[7,8]. Dementia is frequently associated with late-onset epilepsy, and late-onset epilepsy is associated with clinical evidence of dementia[9–11]. Serial EEGs may reveal diffuse abnormalities and slowing of the dominant rhythm associated with the decline of cortical functions[12].

In a meta-analysis of prevalence studies, the age distribution of dementia onset in DS was unimodal, with mean age of onset 51.7 years (SD 7.1, range 31–68), and earlier onset in women[13]. Age-specific prevalence rates of dementia in population-based samples were: age 30–39, 2.0–3.4%; age 40–49, 9.4–10.3%; age 50–59, 36.1–40%; and age 60–69, 54.5%[14–16]. DS subjects aged 50 years or over were significantly impaired on memory tests compared with younger subjects[17]. Dementia rates were increased in elderly people with learning disabilities (LDs) as a whole[18] but the rates in DS were higher[19]. Persons with DS and dementia are also reported to show more non-cognitive symptoms than other persons with LDs and dementia[20]. Dementia contributed significantly to decline in adaptive behaviour and skills after age 40, independently of age, while absence of medical illness had a favourable effect[21].

Longitudinal Studies

Adaptive behaviour deteriorates more in DS than in matched controls with other LDs[22]. Treatable conditions, such as

for multiple diseases, and therefore for generalized morbidity, and increased the risk of mortality from multiple causes. This translates into increased burden on the health care delivery system and higher costs.

Apolipoprotein E is a major serum lipoprotein involved in cholesterol metabolism. Lipoproteins derived from E4 are cleared more efficiently from the blood than those derived from E3 and E2. Apolipoprotein E does not cross the blood–brain barrier but is synthesized in the brain by astrocytes. Down's Syndrome and Alzheimer's Disease: Update

David W. K. Kay and Brian Moore
University of Newcastle upon Tyne, UK

One of the unresolved questions for the dementia of Down's syndrome (DS) as a model for Alzheimer's disease (AD) is the long interval, often up to 20 years, that separates the appearance of the AD pathology in the brains of individuals dying after the age of 35 from the clinical manifestations of dementia.

EPIDEMIOLOGY OF DEMENTIA

Study of decline and dementia is important for service as well as theoretical reasons. The life expectancy of a 1 year-old DS child with mild/moderate handicap is now 55 years[2]. However, the wide variation in premorbid abilities and the presence of physical, particularly sensory impairments[1] often makes the diagnosis of dementia difficult. With ICD-10 criteria as standard, the Dementia Questionnaire for Persons with Mental Retardation[3] and the Dementia Scale for Down Syndrome[4] both perform well, but the Mini-Mental State Examination is too difficult[5]. Both caregiver information and longitudinal monitoring of cognitive performance are desirable[6]. Cortical atrophy may be demonstrated by brain imaging[7,8]. Dementia is frequently associated with late-onset epilepsy, and late-onset epilepsy is associated with clinical evidence of dementia[9–11]. Serial EEGs may reveal diffuse abnormalities and slowing of the dominant rhythm associated with the decline of cortical functions[12].

In a meta-analysis of prevalence studies, the age distribution of dementia onset in DS was unimodal, with mean age of onset 51.7 years (SD 7.1, range 31–68), and earlier onset in women[13]. Age-specific prevalence rates of dementia in population-based samples were: age 30–39, 2.0–3.4%; age 40–49, 9.4–10.3%; age 50–59, 36.1–40%; and age 60–69, 54.5%[14–16]. DS subjects aged 50 years or over were significantly impaired on memory tests compared with younger subjects[17]. Dementia rates were increased in elderly people with learning disabilities (LDs) as a whole[18] but the rates in DS were higher[19]. Persons with DS and dementia are also reported to show more non-cognitive symptoms than other persons with LDs and dementia[20]. Dementia contributed significantly to decline in adaptive behaviour and skills after age 40, independently of age, while absence of medical illness had a favourable effect[21].

Longitudinal Studies

Adaptive behaviour deteriorates more in DS than in matched controls with other LDs[22]. Treatable conditions, such as

depression and medical illness, may be involved[23], but dementia is the main cause; in the absence of dementia and physical illness no decline was found[24]. However, the incidence of cognitive decline and dementia seems to be very sensitive to the criteria used. Adults aged 22–56 who were dementia-free at baseline showed little change over a period of 3–4 years in most cases[25] and even over 6 years, persons aged 50 and over showed, on average, only very slight decreases in cognitive performance, attributed to precocious ageing; only 4% satisfied the criteria for dementia[26]. However, on a sophisticated neuropsychological test battery, 28% of testable persons aged 30+ were deemed to show cognitive deterioration after 4 years, and of those aged over 50 only 30% showed no cognitive decline; as in AD, memory and learning were affected early[27]. Whether persons with DS age prematurely or whether they age normally but are at increased risk of AD remains controversial. Further national and cross-national studies of the prevalence, incidence and natural history of dementia in both DS and in other LD are required[28].

NEUROPATHOLOGY AND GENETICS

The gene coding for familial Alzheimer's disease is now known to be distinct from the amyloid precursor protein (APP) gene, which is also situated on the long arm of chromosome 21. Overexpression of the triplicated APP gene results in higher concentration of APP in DS brains than in brains of elderly controls or of patients with AD[29]. The increased amyloid deposition in AD could be due to some cases of AD being trisomy-21 mosaics, resulting from non-dysjunction during mitosis; such cases might possess other features of DS[30]. A shared susceptibility to non-dysjunction and AD could account for an increased risk of dementia reported among the mothers of persons with DS[31]. Meta-analysis of seven studies of the ApoE polymorphism in DS found a similar distribution between DS adults and non-retarded controls, and no significant difference between DS persons with and without dementia[32]. There were, however, trends for the $\epsilon 2$ allele to be associated with later onset of dementia and later age at death in non-dementing persons, and for the $\epsilon 4$ allele to be associated with earlier onset. Cognitive decline in DS may be influenced by an unidentified gene situated at D21S11[33].

Clinico-pathological Correlations

The first change is the deposition of β-amyloid peptide (β/A4) in the cerebral cortex and elsewhere, in the form of diffuse, amorphous plaques, and may be seen as early as the second or third decade; soon afterwards microglial cells and ubiquitin protein can be detected, and by the age of 35 years "cored" amyloid deposits are seen at post mortem in most subjects[34]. At this stage neurofibrillary tangles (NFT) are numerous in parts of the hippocampus and amygdala but are seen only in isolated cortical neurons. Eventually, and usually after the age of 50, the distribution and density of senile plaques and NFT and loss of neurons conform to the pattern seen in AD[34]. This is the age when clinical dementia usually appears[13]. This gradual evolution of pathological change partly explains the puzzling temporal discrepancy between the onset of pathological and clinical manifestations of dementia in DS. Whether or not a similar evolution of neuropathological change occurs in AD is still unknown.

International Criteria for Alzheimer's Disease and Their Problems—ICD-10, DSM-IV and NINCDS–ADRDA

Kenneth Rockwood
Dalhousie University, Halifax, Nova Scotia, Canada

Dementia often comes to attention when an elderly person's cognition or behaviour no longer conforms to what is expected. Given inherent variability in people and their circumstances, in their past and present performance, in how this matters, in the expectation of changes with age, it is no surprise that how dementia is described, whether it is attributed to Alzheimer's disease (AD), and what that is taken to mean will vary within and across societies[1]. Comparing three sets of commonly-used criteria for AD shows that while each conceptualizes dementia similarly, differences in their literal application can give highly variable results. Such specious variability distracts from the important task of better understanding heterogeneity in disease expression—especially in the presence of medical and psychiatric co-morbidity.

THE THREE SETS OF CRITERIA

The criteria of the National Institute of Neurological and Communicative Disorders and Stroke, and the Alzheimer's Disease and Related Disorders Association (NINCDS–ADRDA)[2] require a clinical examination to produce evidence of dementia, defined as progressive deficits in memory and other areas of cognition (notably language, motor skills and perception) that occurs without a disturbance of consciousness, and in the absence of "systemic disorders other than brain diseases that in and of themselves could account for the deficits". The criteria also require that the onset be between ages 40 and 90, the initial examination include a standardized cognitive test, and the deficits be "confirmed by neuropsychological tests". "Exclusion of causes of dementia other than Alzheimer's" allows a diagnosis of *probable* AD, with neuropathological confirmation required to make the diagnosis *definitive*. *Possible* AD exists when "atypical" features or other co-morbid illnesses exist.

The 10th International Classification of Diseases (ICD-10) has both clinical guidelines[3] and research criteria[4] for Mental and Behavioural Disorders. AD is classed as a dementia, defined as progressive impairment, in the absence of clouding of consciousness, of multiple higher cortical functions, specified as: memory, thinking, orientation, comprehension, calculation, learning capacity, language and judgement. Interestingly, the criteria also note that non-cognitive features ("deterioration in emotional control, social behaviour, or motivation") can accompany or even precede dementia. The diagnosis is one of exclusion; only insidious onset and slow deterioration are cited as characteristic of AD. Subtypes include early and late onset, and "atypical or mixed". The research criteria specify mild, moderate and severe stages, based chiefly on the extent of memory loss, although the impact on daily activities is noted.

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of the American Psychiatric Association defines dementia as "multiple cognitive deficits that include memory impairment and at least one of . . . aphasia, apraxia, agnosia, or a disturbance in executive functioning", provided that such deficits cause impairment, "occupational or social functioning" and represent a decline[5]. The criteria for "Dementia of the Alzheimer's Type" emphasize the need to rule out other conditions, and to exclude the syndrome if it exists only in the setting of delirium. Subtypes include early and late onset, and each of coincident delirium, delusions, and depressed mood. The accompanying text emphasizes insidious onset and gradual decline, notes that (but does not specify how) "cultural background" should be taken into account, and, while recognizing differences in levels of disability, provides no specific criteria for staging.

PROBLEMS WITH CURRENT CRITERIA

Despite cross-national studies of their individual reliability and validity[6] variability in diagnostic criteria can have profound

International Criteria for Alzheimer's Disease and Their Problems—ICD-10, DSM-IV and NINCDS–ADRDA

Kenneth Rockwood
Dalhousie University, Halifax, Nova Scotia, Canada

Dementia often comes to attention when an elderly person's cognition or behaviour no longer conforms to what is expected. Given inherent variability in people and their circumstances, in their past and present performance, in how this matters, in the expectation of changes with age, it is no surprise that how dementia is described, whether it is attributed to Alzheimer's disease (AD), and what that is taken to mean will vary within and across societies[1]. Comparing three sets of commonly-used criteria for AD shows that while each conceptualizes dementia similarly, differences in their literal application can give highly variable results. Such specious variability distracts from the important task of better understanding heterogeneity in disease expression—especially in the presence of medical and psychiatric co-morbidity.

THE THREE SETS OF CRITERIA

The criteria of the National Institute of Neurological and Communicative Disorders and Stroke, and the Alzheimer's Disease and Related Disorders Association (NINCDS–ADRDA)[2] require a clinical examination to produce evidence of dementia, defined as progressive deficits in memory and other areas of cognition (notably language, motor skills and perception) that occurs without a disturbance of consciousness, and in the absence of "systemic disorders other than brain diseases that in and of themselves could account for the deficits". The criteria also require that the onset be between ages 40 and 90, the initial examination include a standardized cognitive test, and the deficits be "confirmed by neuropsychological tests". "Exclusion of causes of dementia other than Alzheimer's" allows a diagnosis of *probable* AD, with neuropathological confirmation required to make the diagnosis *definitive*. *Possible* AD exists when "atypical" features or other co-morbid illnesses exist.

The 10th International Classification of Diseases (ICD-10) has both clinical guidelines[3] and research criteria[4] for Mental and Behavioural Disorders. AD is classed as a dementia, defined as progressive impairment, in the absence of clouding of consciousness, of multiple higher cortical functions, specified as: memory, thinking, orientation, comprehension, calculation, learning capacity, language and judgement. Interestingly, the criteria also note that non-cognitive features ("deterioration in emotional control, social behaviour, or motivation") can accompany or even precede dementia. The diagnosis is one of exclusion; only insidious onset and slow deterioration are cited as characteristic of AD. Subtypes include early and late onset, and "atypical or mixed". The research criteria specify mild, moderate and severe stages, based chiefly on the extent of memory loss, although the impact on daily activities is noted.

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of the American Psychiatric Association defines dementia as "multiple cognitive deficits that include memory impairment and at least one of . . . aphasia, apraxia, agnosia, or a disturbance in executive functioning", provided that such deficits cause impairment, "occupational or social functioning" and represent a decline[5]. The criteria for "Dementia of the Alzheimer's Type" emphasize the need to rule out other conditions, and to exclude the syndrome if it exists only in the setting of delirium. Subtypes include early and late onset, and each of coincident delirium, delusions, and depressed mood. The accompanying text emphasizes insidious onset and gradual decline, notes that (but does not specify how) "cultural background" should be taken into account, and, while recognizing differences in levels of disability, provides no specific criteria for staging.

PROBLEMS WITH CURRENT CRITERIA

Despite cross-national studies of their individual reliability and validity[6] variability in diagnostic criteria can have profound

effects on resulting epidemiological[7] and clinical[8] estimates. This is especially true with strict exact adherence to each criterion, e.g. when patients whose dementia is too severe to sit for neuropsychological tests are said not to have fulfilled the NINCDS–ADRDA criterion that such tests be administered. Now while it might be argued that there is no point in criteria except in having strict adherence to them, we cannot ignore that most such criteria are revised periodically, and that the operationalization of some criteria (notably, functional impairment) can vary widely, again with marked impact on the resulting estimates[9]. A better approach would be to make clear how the interpretation of specific criteria may affect a study's results[7].

Each set of criteria views AD as a diagnosis of exclusion. Given that AD is common and that many of the diagnoses to be excluded are rare, this approach seems perverse, despite the absence of a biological marker for the most common disorder. Perhaps it is the lack of a detailed consideration of staging, another problem with all the criteria, that has resulted in the "diagnosis of exclusion" approach. Without some understanding of systematic variation by stage, the heterogeneity of AD would seem chaotic, so that the clinician could only feel confident in the diagnosis when everything else had been rejected. By contrast, recognizing common features in how AD presents and progresses makes the task of diagnosing it with confidence much easier—indeed, where characteristic milestones are present, such confidence can extend even to a retrospective diagnosis[10]. This notion of a usual progression is, in fact, implicit in considerations of "atypical presentations", which usually are understood as deficits (*e.g.* aphasia, apraxia) that occur at an *uncharacteristically early* stage. Also, in emphasizing insidious onset, the criteria seem to exclude patients whose dementia initially presents with delirium, despite that sequence being a common path to AD[11].

Each set of criteria emphasizes a categorical approach to diagnosis, despite patients who often show more than one problem—typically AD and cerebrovascular problems[12]. While each set of criteria allows for "mixed diagnoses", they appear to underestimate the role of cerebrovascular lesions in both the risk of AD and the degree of its expression[13].

In practice, each set of criteria sees AD chiefly in cognitive terms. Another way to think of dementia, however, is as a decline of "effective behaviour"[14]—a phenomenon seen often in clinical practice, in which cognitive and non-cognitive changes can compete for prominence as the complaints of patients and families. Perhaps it is this experience which underlies the recognition of non-cognitive features in the ICD-10 clinical description, or in the DSM-IV subtypes. Nevertheless, these non-cognitive aspects have not much informed our research understanding of disease presentation, and neither are they likely to. Given the ongoing search for clinical correlates of structural or chemical preclinical features, cognitive deficits (which are readily quantifiable) are likely to achieve even greater prominence. Both the near-continuous distribution in neuropsychological test performance scores across an unimpaired to demented range[15,16] and the preference for categories mean that we are more likely to see a renewed "cut points" debate than a debate over the meaning of cognitive vs. non-cognitive symptoms as the basis for future revisions of diagnostic criteria for AD.

The Neuropathology of Alzheimer's Disease

David M. A. Mann

University of Manchester, Manchester UK

Alzheimer's disease (AD) is the most common cause of dementia at any time of life and, although the brains of patients with this disorder show remarkable pathological changes, the nosological status of these and their relevance to the underlying neurodegenerative process has been the subject of vigorous debate. In this chapter the gross and microscopical changes of AD will be described.

IMAGING STUDIES

Structural imaging, by CT or MRI, fails to reveal changes in the brain specific to AD. Usually there is evidence of widespread cortical atrophy and ventricular enlargement, although not in a way that obviously discriminates AD from other neurodegenerative dementing disorders. A more severe medial temporal atrophy has been claimed to distinguish AD from normal ageing[1], although this does not differentiate between AD and other disorders, such as frontotemporal dementia, where a similar degree of hippocampal atrophy is seen[2,3]. Functional imaging, using PET or SPECT, reveals a conspicuous biparietal deficit in many patients with AD, although not all individuals show this and this pattern can also be seen in patients with Lewy body dementia[4]. Hence, definitive diagnosis still remains the province of histopathology, although this is usually made retrospectively following the death of the affected person.

THE AUTOPSY APPEARANCE OF THE BRAIN

Although the pattern of atrophy in AD may be quite distinct from that of the normal elderly[2,5] and of other dementing disorders of diverse aetiology[3,6] the diagnosis cannot be made at autopsy from visual inspection alone. Nonetheless, brain weight is usually reduced due to cortical atrophy (shrinkage of the gyri and widening of the sulci), which can be widespread but most often is severe in the medial temporal regions, particularly the parahippocampal gyrus, while the occipital lobe and the motor cortex are generally spared[2].

The cortical grey matter is reduced in thickness and the white matter, while macroscopically normal in appearance, is lost proportionately to that of the grey matter[2]. The ventricular system is dilated, most markedly in the temporal horns of the lateral ventricles. The substantia nigra usually shows normal pigmentation but frequently there is loss of pigment from the locus caeruleus. Cerebrovascular changes are often coincidentally present, but do not necessarily indicate a multi-infarct dementia.

HISTOPATHOLOGICAL CHANGES

The histopathology of AD displays several abnormalities and, although these changes can also be found in the brains of most normal elderly individuals, it is their greater extent and severity and regional pattern of distribution that is characteristic of AD.

Amyloid Plaques

These are aggregates (plaques) of an amyloid protein—amyloid β protein (Aβ)—typically 50–200 μm in diameter, within the cerebral cortex and other grey matter regions of the brain. The Aβ may be surrounded by abnormal presynaptic nerve cell processes called dystrophic neurites. The same protein is often present within the walls of leptomeningeal and intracortical blood vessels, causing an amyloid angiopathy. Four plaque types have been identified[7]:

1. *Diffuse* plaques have even Aβ deposition with ill-defined borders, not forming discrete rounded masses. They are the most common plaque type in AD and can only be defined by immunohistochemical staining with antibodies to Aβ; they have no dystrophic neurites.
2. *Primitive* plaques are discrete rounded Aβ deposits without a dense core but having some dystrophic neurites. They can be stained using conventional amyloid stains.
3. *Classical* plaques have a dense star-shaped Aβ core surrounded by a corona of radiating wisps of Aβ and many dystrophic neurites.
4. *Compact* or *burnt-out* plaques have dense Aβ cores without a surrounding corona, or neurites.

Primitive and classical plaques with dystrophic neurites containing PHF are termed "neuritic plaques", synonymous with what used to be known as "senile plaques". Synapse loss occurs from primitive and classical plaques, but not diffuse plaques[62].

Neuritic, but not diffuse, plaques contain reactive astrocytes and activated microglial cells[8,9]; the latter may play a role in the "processing" of Aβ during plaque evolution. Although unproved, the prevailing view is that amyloid plaques undergo, during their prolonged life history, a series of evolutionary changes from diffuse to cored plaques. This involves not only compositional changes in Aβ, but also changes in associated glial cells. This evolutionary process has largely been deduced from studies of persons with trisomy 21 (Down's syndrome) dying at different ages[9,10], who inevitably develop the histopathology of AD if they live past 50 years of age.

Although plaques are always most dense in cerebral cortex, they can also be numerous in white matter and subcortical areas, including the basal ganglia and cerebellum, where the deposits may be associated with dystrophic neurites but not PHF[11]. Plaques are common in the cerebral cortex in normal ageing, even in high density in some cognitively normal elderly patients[12,13], but are generally of the diffuse or primitive types[14,15]. The number of plaques, especially those containing $A\beta_{40}$, is increased in a gene dose-dependent way in the presence of the $\varepsilon4$ allele of the apolipoprotein gene[16,17].

$A\beta$ is derived, by proteolytic cleavage, from a large precursor, the amyloid precursor protein (APP). This is a transmembrane protein with a large extracellular amino-terminal portion and a small intracellular carboxy-terminal stub. $A\beta$ protein is present in plaque amyloid as a heterogeneous mix of cleaved APP fragments, 39–43 amino acids long[18,19].

APP is catabolized by enzymes known as "secretases". One enzyme, α-secretase (a metalloprotease)[20,21] cleaves APP across the middle of its transmembrane domain and in this way $A\beta$ formation is not possible. Another enzyme, β-secretase (a transmembrane aspartic protease), termed β-site APP-cleaving enzyme (BACE)[22], cuts APP at the amino-terminus of the $A\beta$ domain. The $A\beta$ peptide can then be released from this carboxy-terminal stub by a third enzyme, γ-secretase—which requires presenilin-1 protein for its activity, acting around amino acids 40–43 of the $A\beta$ sequence. The major catabolic product of these enzyme activities is $A\beta_{40}$, with lesser quantities of the longer peptide $A\beta_{42}$. However, because of a higher propensity to form amyloid fibrils the predominant, and indeed the sole, $A\beta$ species in diffuse plaques of the cerebral cortex, corpus striatum and cerebellum is $A\beta_{42}$: $A\beta_{40}$ is mostly present within the cored, neuritic plaques[23]. Paradoxically, the predominant peptide within blood vessel walls is $A\beta_{40}$, with variable, and usually much lesser, amounts of $A\beta_{42}$[24]. Studies on Down's syndrome[25] indicate that $A\beta_{42}$ is the earliest peptide deposited, $A\beta_{40}$ deposition occurring subsequently within that subset of diffuse plaques evolving into cored plaques[23].

Some cases of familial AD result from point mutations in the APP gene ($APP_{670/671}$ and APP_{717}) on chromosome 21[26], whereas in others mutations in genes on chromosomes 14 and 1, known as presenilin-1 and presenilin-2, respectively, are responsible[27]. Clinicopathological studies indicate that these familial AD cases have an especially high tissue deposition of $A\beta$, particularly $A\beta_{42}$, and very severe amyloid angiopathy[28,29]. Facilitation of $A\beta$ deposition, particularly $A\beta_{42}$, may be the mechanism whereby the APP and presenilin mutations operate. A different mutation in the APP gene (APP_{693}) causes hereditary cerebral haemorrhage with amyloidosis (Dutch type)[30].

Neurofibrillary Tangles (NFT)

NFT are abnormal filamentous inclusions that form inside nerve cells. They are not specific to AD and are seen in other neurodegenerative disorders, as well as being present (in lower numbers) in the brains of elderly non-demented persons, particularly in the hippocampus and temporal cortex[31,32]. Typically, NFT are found in temporal, frontal and parietal cortical areas with sparing of the paracentral (sensory and motor) and occipital cortices. They occur in subcortical areas such as the hypothalamus and nucleus basalis of Meynert, as well as in the dorsal raphe and locus coeruleus. When NFT formation in these regions is severe, NFT can be seen in the substantia nigra, thalamus and basal ganglia[18].

Traditionally, NFT are demonstrated by silver staining, but they can also be detected immunohistochemically using antibodies to their constituent proteins. The classical NFT is a flame-shaped skein of fine fibrils occupying much of the cell body. In haematoxylin and eosin-stained preparations, NFT are faint basophilic fibrillar inclusions. Certain NFT, termed "ghost tangles", appear eosinophilic and represent liberated neuropil remains following death of the affected neurone. Rounded ball-like NFT are termed "globose tangles" and are most common in neurones of the brainstem nuclei, but also in smaller cortical neurones[18].

Ultrastructurally, NFT are composed of pairs of filaments, diameter 20 nm, twisted with a periodicity of 80 nm, hence termed paired helical filaments (PHF)[33]. Evidence suggests them to be a ribbon-like double helical stack of transversely-arranged subunits[34].

NFT are composed of at least two major proteins, tau[35–37] and ubiquitin[38,39]. Tau protein stabilizes the microtubular cytoskeleton. The tau protein in PHF is abnormally phosphorylated[40,41] and abnormalities in protein phosphorylation may be fundamental to the neurodegenerative process of AD[42]. Ubiquitin labels cell proteins for degradation[70] and its presence in PHF is presumably targeting the abnormal protein for (attempted) degradation.

Like plaques, NFT undergo evolutionary changes that correlate with their morphology and immunoreactivity[43]:

Stage 0: amorphous tau immunoreactivity without aggregation into filaments (pre-tangles).
Stage 1: delicate fibrillar structures immunoreactive for tau and ubiquitin.
Stage 2: skeins and whorls of densely aggregated filaments, immunoreactive for tau and (sometimes) ubiquitin, filling the nerve cell body and displacing the nucleus.
Stage 3: extracellular NFT without tau immunoreactivity but ubiquitin-positive. The NFT is infiltrated by astrocytic processes, and $A\beta$ may be deposited upon the filaments[44].

The progress of AD can be staged by following the spread of NFT from hippocampal regions to neocortex and subcortex[45].

Neuropil threads are abnormal nerve cell processes (dystrophic neurites) in the neuropil of the cerebral cortex, not associated with plaques[46]. They are swollen, distorted structures containing PHF[47], antigenically similar (for tau and ubiquitin) to, and probably contiguous with, the NFT in neurones. These abnormal processes may interfere with neuronal communication, contributing to the cortical deficit.

The importance of neurofibrillary pathology in AD has been underscored by the discovery that similar abnormal tau aggregates occur in neurones and glia in frontotemporal dementia[48], due to mutations in the tau gene[49–51]. These mutations alter the microtubule binding capacity of tau, favouring self-assembly of the mutated protein into pathological structures, or they change the expression pattern of the tau gene, leading to intracellular accumulations of tau isoforms with four microtubule binding repeat domains. Pathological tau aggregates are also formed in a related condition, progressive supranuclear palsy[52], in the absence of $A\beta$ deposition. Neurodegenerative disease leading to dementia can therefore be caused by neurofilamentous aggregations of tau *alone*, irrespective of whether amyloid plaques are present. That is not to say, however, that $A\beta$ deposition in AD is of no importance. This may represent the route towards the formation of abnormal tau in this particular disorder, whereas in other conditions other pathways to tau pathology are invoked. Nonetheless, once pathological tau is formed and accumulated, a common mechanism of cell death may be set up in all "tauopathies" and this clearly has profound therapeutic implications for AD and other dementing disorders.

Granulovacuolar Degeneration (GVD)

GVD is an accumulation of membrane-bound vesicles, containing amorphous material, within nerve cells. In haematoxylin and

eosin- or silver-stained sections GVD appears as numerous dot-like particles, each with a surrounding clear halo. These bodies may also be seen in ageing brains, but their number and tissue density are considerably greater in AD. Some granulovacuoles are immunoreactive for ubiquitin[53,54] and they may represent residual bodies from lysosomal-mediated proteolysis[55].

Hirano Bodies

These are rod-shaped bodies, 15 μm wide and 60–100 μm long, that appear in neurones with ageing but, again, with greater density in AD. They are brightly eosinophilic and immunohistochemistry suggests they are derived from the cytoskeletal protein, actin[56].

Neuronal loss in AD

There is conspicuous loss of neurones from the cerebral cortex and hippocampus in AD, particularly large pyramidal cells[57–59]. This loss is more marked in younger patients (<80 years), although it is still significant in older individuals[59]. Golgi studies show loss of dendritic arborization in surviving neocortical cells[60] and electron microscopy and immunohistochemistry indicate considerable synapse loss[61–63]. Cell loss from the nucleus basalis of Meynert, the cholinergic input into the cortex, is reflected neurochemically by reduced choline acetyltransferase, and that from the locus coeruleus can be related to a decline in cortical noradrenaline[64].

Amyloid Angiopathy

The deposition of Aβ in cerebral arteries, termed "amyloid angiopathy" or "congophilic angiopathy", is almost invariable in AD but can also exist in its own right. This amyloid angiopathy may sometimes be responsible for (lobar) cerebral haemorrhage, a cause of secondary stroke in AD[65–67].

White Matter Changes

A reduction in the amount of white matter in AD is associated with a decrease in the intensity of myelin staining. This has been described as incomplete infarction[68,69] and, although it may mimic Binswanger's disease pathologically and on imaging, it is not associated with lacunar infarcts or hypertensive arteriosclerosis. Such white matter changes may sometimes be related to ischaemia due to amyloid angiopathy, but bouts of systemic hypotension might also be causal.

Oxford Project to Investigate Memory and Ageing (OPTIMA): a Longitudinal Clinicopathological Study of Dementia and Normal Ageing

A. David Smith
OPTIMA, Oxford, UK

OPTIMA was founded in 1988 by A.D. Smith, K.A. Jobst, E.M.-F. King and M.M. Esiri, with the aim of studying in parallel a cohort of patients with memory problems and age-matched controls. The total number of subjects at the end of 1999 was 666, of which 361 are patients with dementia. OPTIMA is a longitudinal clinicopathological study and its main strength lies in the very high necropsy rate (94% of the 207 who have died), which permits correlation of findings in life with those of neuropathology. Each year each subject has a full clinical examination, lumbar puncture, neuropsychology (the CAMDEX, supplemented by other tests), CT scans (axial and temporal lobe-orientated) and SPECT scans (Ceretec, for cerebral blood flow). A subset of 155 subjects have had annual volumetric MRI scans and more detailed neuropsychology.

The main findings so far are:

- Comparison of standard clinical diagnostic procedures with histopathological diagnosis, showing the poor accuracy of current clinical diagnostic procedures[1].
- Development of a more accurate diagnostic procedure for Alzheimer's disease (AD) in life by a combination of structural (CT) and functional (SPECT) brain imaging[2].
- Recognition that AD is distinct from ageing and is a true disease that follows a "catastrophic event" in the brain, leading to atrophy of the medial temporal lobe[3].
- Discovery of a biological "state" marker, the thickness of the medial temporal lobe, that can be used to follow the progression of AD[4].
- Discovery that nerve cells in AD brain express markers of the cell division cycle[5].
- Recognition of the additive effect of minor cerebrovascular disease and AD-type pathology in clinical dementia[6,7].
- Identification of a gene (K variant of butyrylcholinesterase) that markedly increases the risk of AD in those who also have the ApoE4 gene[8].
- Discovery of a risk factor (elevated blood levels of homocysteine) for AD and for vascular dementia that is potentially modifiable by diet[9].
- Finding that raised blood homocysteine levels are associated with low performance on cognitive tests in the normal elderly[10].

Projects currently under way include the search for further genetic and non-genetic risk factors for dementia, with particular emphasis on modifiable risk factors; a pilot clinical trial of high-dose folic acid and vitamin B_{12} in subjects with dementia (together with Professor G. Wilcock, Bristol); development of novel memory tests to detect pre-symptomatic AD; use of sub-voxel co-registration MRI scans to follow progression of AD over a period of a few months (with Professor G. Bydder, Hammersmith Hospital).

The current Director of OPTIMA is Professor A. David Smith, the Clinical Director is Professor Robin Jacoby and the Operational Manager and Senior Nurse is Mrs Elizabeth King. Funding is from Bristol–Myers Squibb, the Medical Research Council, National Health Service R&D and several charities.

Consortium to Establish a Registry for Alzheimer's Disease (CERAD)

Gerda G. Fillenbaum and Albert Heyman
Duke University Medical Center, Durham, NC, USA

CERAD was funded by the National Institute on Aging in 1986 to develop a battery of standardized instruments for the evaluation of patients with Alzheimer's disease (AD). Until that time clinical investigation of AD and comparison of research findings was hampered by the absence of standardized assessment and uniform diagnostic criteria. The assessments developed by CERAD have been evaluated on over 1000 patients with AD and nearly 500 control subjects, seen at 24 major University medical centers across the USA. Because of their sensitivity to dementia, they have also been used in epidemiologic surveys of the elderly, to aid in identification and staging of those with dementia. The measures permit uniform identification of dementia and standardized assessment of AD.

CERAD has developed and evaluated three primary assessments. These include a clinical battery, a neuropsychological battery, and a neuropathological assessment. An overview of the contents of these assessments is given in Table 1. In addition, specialized assessments have been developed to assess family history of AD, Parkinson's disease, and Down's syndrome; extrapyramidal dysfunction in AD; neuroimaging; behavioral pathology; and assessment of service use.

Videotapes demonstrating administration of these measures are available. Educational brochures on memory loss, AD, the importance of autopsy, and an autopsy resources packet to help sites, have been prepared. Many of the CERAD assessments have been translated into various European and Asian languages, and are in use internationally.

A brief but extensive review of CERAD, including a bibliography covering the first 10 years, has been published[1]. Multiyear data on CERAD patients and control subjects as well as the CERAD measures, are available on CD-ROM. This and additional information can be obtained by writing to the Principal Investigator, Dr A. Heyman, CERAD, Box 3203, Duke University Medical Center, Durham, NC 27710, USA.

Table 1. Overview of the contents of the primary CERAD assessments

Clinical battery	*Neuropsychological battery*
Demographic data on subject and informant	Verbal fluency
Clinical history, including cognitive function, systemic disorders, cerebrovascular history, parkinsonism, depression, drug effects	Modified Boston Naming Test
Blessed Dementia Scale (ADL)	Mini-Mental State Examination
Screen for Behavior Rating Scale for Dementia (BRSD)	Word list memory
Short Blessed, Calculation, Clock, Language	Constructional praxis
Clinical examinations, including brief physical, overall neurological assessment, extrapyramidal dysfunction	Word list recall
Laboratory and imaging studies	Word list recognition
Clinical diagnosis, including CDR staging, diagnostic impression for:	Constructional praxis recall
Possible dementia prodrome	The following are used as needed:
Probable and possible AD	Shipley Scale
Non-AD dementias	Wechsler Memory Scale, Paired Association I
	Trail Making, A and B
	Wechsler Memory Scale, Paired Association II
	Nelson Adult Reading Test
	Finger tapping
	Verbal fluency (F and P words)
	Neuropathology Assessment
	Demographic information and history
	Gross examination
	Cerebrovascular disease (gross)
	Microscopic findings: vascular; major non-vascular; hippocampus and neocortex
	Neurohistologic findings
	Neuropathological diagnoses
	Final assessment

Neurotransmitter Changes in Alzheimer's Disease: Relationships to Symptoms and Neuropathology

Paul T Francis[1] and Elaine K. Perry[2]

[1] *Centre for Neuroscience Research, King's College London, UK,*
and [2]*MRC Building, Newcastle upon Tyne General Hospital, UK*

Cell death and histopathological changes affecting a number of neuronal systems are considered to result in the development of the typical symptomology of Alzheimer's disease (AD), characterized by gross and progressive impairments of cognitive function, which are often accompanied by behavioural disturbances such as aggression, depression, psychosis, apathy and wandering. Such non-cognitive behavioural symptoms are also considered to relate to structural and functional alterations in neurotransmission. Carers find behavioural disturbances difficult to cope with and the presence of such behaviours in AD patients often leads to the need for institutionalization[1]. The challenge has been to identify changes in specific neurotransmitter systems that underlie cognitive impairment and particular behavioural problems and to develop rational therapeutic strategies.

NEUROCHEMICAL AND HISTOPATHOLOGICAL CHANGES IN AD

The majority of biochemical studies of AD have relied on information derived from post mortem brain which typically represents the late stage of the disease (8–10 years after onset of symptoms). In these studies there is considerable evidence of gross brain atrophy, histopathological features and multiple neurotransmitter abnormalities affecting many brain regions. However, investigations of biopsy tissue taken from AD patients 3–5 years (on average) after the onset of symptoms indicate that a selective neurotransmitter pathology occurs early in the course of the disease[2].

Acetylcholine

Changes affecting many aspects of the cholinergic system in patients with AD have been reported since the initial discovery of deficits in choline acetyltransferase activity in post mortem brains[3–5]. In biopsy samples from AD patients, presynaptic markers of the cholinergic system were also uniformly reduced[2]. Thus, choline acetyltransferase activity, choline uptake and acetylcholine synthesis are all reduced to 30–60% of control values. The clinical correlate of this cholinergic deficit in AD was, until recently, considered to be cognitive dysfunction. Such a conclusion was supported by clinicopathological studies in AD and parallel experiments in non-human primates or rodents, which demonstrated disruptive effects of basal forebrain cholinergic lesions on cognitive functions. Such studies led to the "cholinergic hypothesis of geriatric memory dysfunction"[6].

Furthermore, cholinergic deficits in AD occur to the greatest extent in cortical areas primarily concerned with memory and cognition—the hippocampus, adjacent temporal lobe regions and select frontal areas. In a recent study[7] regional variations in the loss of cholinergic fibres in AD were assessed on the basis of acetylcholinesterase (AChE) histochemistry. Greatest fibre loss (>75%) was apparent in temporal association areas, with various frontal areas, including granular orbitofrontal, dysgranular orbitofrontal, prefrontal association, frontal operculum, prefrontal association and frontal pole, demonstrating fibre losses in the range 45–75%. In other cortical areas, including primary motor, premotor association, anterior and posterior cingulate, fibre loss was less than 45%.

Neuropathologically, loss of neurons from the nucleus of Meynert (Ch4 cholinergic nucleus) is well documented in AD, although the extent of the loss reported varies from moderate to severe, and it has been suggested that in AD cholinergic dysfunction exceeds degeneration[8]. Detailed analysis of subpopulations of cholinergic perikarya in the nucleus basalis have been reported by Mesulam and Geula[9], who identified selective cell loss in Ch4p (the posterior section projecting to temporal cortex). In the intermediate sector, Ch4id, which includes projections to the frontal cortex, neuron loss is not as extensive, consistent with the moderate loss of cholinergic enzyme activity.

On the basis of the above evidence, neocortical cholinergic innervation appears to be lost at an early stage of the disease and this is supported by a recent study[10] in which the cholinergic deficit (reduced ChAT activity) has been related to Braak stageing. Braak stages I and II are considered to represent the earliest presentation of AD, with neurofibrillary tangles in the entorhinal cortex, and a 20–30% loss of ChAT activity was reported in brains from patients at these stages of AD[11]. However, another study using the Clinical Dementia Rating Scale (CDR) suggests that the greatest reduction in markers of the cholinergic system occurs between moderate (CDR 2.0) and severe (CDR 5.0) disease, with little change between non-demented and the mild stage (CDR 0–2)[12].

There has been a recent shift of emphasis regarding the clinical significance of cholinergic deficits. Non-cognitive or neuropsychiatric, in addition to cognitive, symptoms also appear to have a cholinergic component[13]. For example, visual hallucinations relate to neocortical cholinergic deficits[14], such deficits (e.g. loss of ChAT) being greater in Lewy body dementia (DLB), where

hallucinations are common, than in AD where they are less common[15]. Reductions in cortical ChAT activity in patients with dementia, in addition to correlating with cognitive decline, are also related to overactivity and aggressive behaviour[16].

It has also been suggested that acetylcholine is centrally involved in the process of conscious awareness[17], and that the variety of clinical symptoms associated with cholinergic dysfunction in AD and related disorders reflects disturbances in the conscious processing of information. There is evidence that implicit memory, for example (which does not involve conscious awareness), is relatively intact in AD[18,19].

Glutamate

Loss of synapses and pyramidal cell perikarya (both considered to be markers of glutamatergic neurones) from the neocortex of AD patients correlate with measures of cognitive decline[2]. Although neurochemical studies of glutamate neurotransmission have failed to demonstrate extensive alterations, this may be related to the difficulty in distinguishing the transmitter pool of glutamate from the metabolic pool. Nevertheless, glutamate concentration was reduced by 14% in temporal lobe biopsy samples and by 86% in the terminal zone of the perforant pathway at autopsy of AD patients[20]. Uptake of D-aspartate, a putative marker of glutamatergic nerve endings, is also reduced in many cortical areas in AD brain[2]. Thus, additional factors other than impaired cholinergic function are likely to contribute to cognitive impairment in AD. However, it is important to remember that glutamatergic neurones of the neocortex and hippocampus are influenced by acetylcholine through nicotinic and muscarinic receptors[2]. Thus, treatment of patients with cholinomimetics is likely to increase glutamatergic function.

Other neurotransmitters

Using biopsy samples from AD patients, serotonergic and some noradrenergic markers are affected, whereas markers for dopamine, γ-aminobutyric acid (GABA) or somatostatin are not altered. When post mortem studies of AD brain are considered, many neurotransmitter systems, including GABA and somatostatin, are involved or are affected to a greater extent[2]. Based on post mortem studies, however, changes in serotonergic neurotransmission may be linked to the behavioural disturbances of AD, such as depression, rather than cognitive dysfunction. For example, patients with AD who were also depressed had lower numbers of serotonin reuptake sites in the neocortex than did patients without this symptom[21]. Furthermore, both reduced serotonergic[22,23] and increased noradrenergic activities and sensitivity[24,25] have been linked to aggressive behaviour.

Neurotransmitter receptors

Many neurotransmitter receptors appear to be unaltered in AD; however, studies have demonstrated a reduction in the number of nicotinic and muscarinic (M2) ACh receptors, most of which are considered to be located on presynaptic cholinergic terminals. Despite continuing, often unconfirmed, reports of changes in one or more of the muscarinic receptor subtypes ($M–M_5$), it is generally agreed, on the basis of autopsy studies, that the M1 subtype is unchanged until later in the disease when it may decline, probably in relation to cholinoceptive (postsynaptic) neurodegeneration. The status of the other subtypes is not clearly established, primarily due to the lack of specific pharmacological labels. Results using antibodies against the different receptor subtypes, while specific, are complicated by discrepancies between the distribution and density of immunoreactive proteins and localized functional receptors. With respect to muscarinic receptor coupling to G-proteins, most studies using a variety of investigative procedures have identified some degree of uncoupling, especially with respect to the M1 receptor[26].

A highly consistent receptor abnormality in AD is the loss of the nicotinic receptor[27,28], which appears to primarily reflect loss of the α4-containing subtype (generally associated with β2) as opposed to α3 or α7 subtypes[29]. Immunohistochemically, loss of α4 and β2 reactive fibres has been observed in temporal cortex, associated with reactive neuropil threads, tangles and plaques[30].

NEUROIMAGING

With respect to the cholinergic deficit, whilst measurements of CSF acetylcholine, choline and acetylcholinesterase have been reported in AD, such reports are either unconfirmed or inconsistent. More promising and potentially diagnostic findings have been obtained using *in vivo* functional imaging. The vesicular acetylcholine transporter and acetylcholinesterase, imaged using PET and iodobenzovesamicol and *N*-methylpiperidin-4-yl propionate, respectively, are both reduced in AD patients, and furthermore relate to reductions in MMSE[31,32]. Using SPECT, muscarinic QNB binding is reduced in advanced but not early cases[33], and iododexetamide, with preference for M2, is also reduced in mild/early cases[34]. Reductions in nicotine binding have also been detected using PET[35]. *In vivo* observations relating to non-cholinergic systems (principally noradrenaline, 5-HT and dopamine) have been equally inconsistent regarding CSF parameters and, with respect to neuroimaging markers, only dopaminergic markers have so far been investigated and there is, as expected, no consistent abnormality of the transporter or D2 receptor.

LINKS BETWEEN NEUROTRANSMISSION AND NEUROPATHOLOGY

Mismetabolism of amyloid precursor protein (APP) leading to increased production of β-amyloid has been proposed as the critical event in both familial and sporadic AD causing other changes (tangles, neurone loss, synapse loss and neurotransmission dysfunction). Cholinergic neurotransmission may be a specific target for β-amyloid, since it has been shown to reduce both choline uptake and acetylcholine release *in vitro*[36]. Furthermore, β-amyloid is reported to bind with high affinity to the α7 subtype of the nicotinic receptor, suggesting that cholinergic function through this receptor may be compromised because of high levels of (soluble) peptide in AD brains[37].

There is increasing evidence that various neurotransmitter systems are capable of influencing the metabolism of APP, favouring the non-amyloidogenic processing[38]. In particular, stimulation of muscarinic M1 receptors increases APP secretion, while decreasing β-amyloid production[39]. Furthermore, nicotinic receptor stimulation is associated with reduced plaque densities in human brain[40]. These results suggest that compounds being developed for symptomatic treatment may have a serendipitous effect on the continuing emergence of pathology by reducing the production of β-amyloid.

CHOLINERGIC APPROACHES TO TREATMENT

Biochemical studies of postmortem brains from AD patients showing evidence of a substantial presynaptic cholinergic deficit,

which correlated with cognitive impairment[41], together with the emerging role of ACh in learning and memory[6], clearly suggested a rational approach to treatment. However, more recent studies have identified a role for the cholinergic system in attentional processing rather than memory.

A prediction of the cholinergic hypothesis is that drugs that potentiate central cholinergic function should improve cognition in AD patients. There are a number of approaches to the treatment of the cholinergic deficit; however, the use of acetylcholinesterase inhibitors is the most well-developed approach to the treatment of AD to date[42].

During the late 1980s and early 1990s, the first cholinomimetic compound, tacrine, underwent large-scale clinical studies and established clearly the benefits of ChE treatment in patients with a diagnosis of probable AD. Tacrine was subsequently approved for use in some, but not all, countries. Statistically significant, dose-related improvements on objective performance-based tests of cognition, clinician- and caregiver-rated global evaluations of patient well-being and also quality of life measures have been reported[43]. Unfortunately, potentially serious adverse side effects have limited the use of this compound.

A so-called second generation of ChE inhibitors has been developed, including donepezil, rivastigmine, metrifonate and galantamine[42]. Such compounds demonstrate a clinical effect and magnitude of benefit of at least that reported for tacrine, but with a more favourable clinical profile. Furthermore, evidence is emerging from clinical trials of cholinomimetics that such drugs may improve the abnormal non-cognitive, behavioural symptoms of AD. The cholinesterase inhibitors physostigmine, tacrine, rivastigmine and metrifonate have variously been reported in placebo-controlled trials to decrease psychoses (hallucinations and delusions), agitation, apathy, anxiety, disinhibition, pacing and aberrant motor behaviour and lack of cooperation in AD[13,44]. In a recent open-label trial of Exelon (rivastigmine), patients with DLB almost all responded positively on one or more of these measures[45].

CONCLUSIONS

In AD many different pathological manifestations, such as cortical and subcortical β-amyloidosis (plaques), abnormal tau (tangles and dystrophic neurites), neuronal and synapse loss and various transmitter deficits, provide an increasingly complex framework for clinical–neuropathological correlations. It is therefore unlikely that cholinergic deficits alone will account for the full spectrum of cognitive and non-cognitive symptoms seen in AD. In these circumstances it is perhaps surprising that cholinomimmetic therapy has been a modest success in many patients, improving cognitive and non-cognitive symptoms and activities of daily living. Such therapy is all that is available at present and may well still be required as new therapies designed to slow disease progression come into the clinic.

Antemortem Markers

Susan J. Van Rensburg, Felix C. V. Potocnik and Dan J. Stein

Tygerberg Hospital and University of Stellenbosch Medical School, South Africa

INTRODUCTION

It has become increasingly clear that the disease process of Alzheimer's disease (AD) is multifaceted. It is thus difficult to single out any particular factor as the root cause of the disease, since AD appears to be a complex disorder involving several genes interacting with environmental factors. Apart from the familial forms of the disease, in which the gene mutations have been elucidated, many proteins, enzymes and other factors are involved in the process of neurodegeneration, in the formation of plaques and tangles and in the development of an inflammatory state of the brain. In all, more than 100 proteins and other factors have been found to be altered in AD patients compared with controls.

For all that, very few markers suitable for antemortem diagnostic purposes have emerged, since many of the abovementioned alterations are not specific for AD, while others pertain only to subsets of AD[1]. While it has been argued that the most powerful antemortem marker in AD is a clinical diagnosis based on an adequate range of observations[2], such diagnosis is at present to some degree still one of exclusion. An ideal biological marker would allow for greater specificity and sensitivity than clinical diagnosis, and be readily obtainable. While neuropathological biopsy diagnosis of AD allows specificity and sensitivity, it is rarely clinically warranted or available. The neurobiological alterations present in AD may be reflected in changes in cerebrospinal fluid (CSF) neurotransmitters or neurochemicals, or in a change in systemic tissues, including blood constituents. It should be borne in mind, however, that CSF measurements are influenced by a variety of factors, including CSF gradients, age and sex, diurnal and seasonal variation, state of the blood–brain barrier, blood contamination, contributions from the spinal cord, phase of illness, psychomotor activity, stress and diet. Measurement of blood constituents may also reflect concentration differences due to diurnal rhythms and other factors.

In this chapter on antemortem markers, we will briefly review neurotransmitters and neurochemistry, systemic pathology and brain imaging.

NEUROTRANSMITTERS AND NEUROCHEMISTRY

The Cholinergic System

The most effective drugs so far for the treatment of AD are the acetylcholinesterase (AChE) inhibitors. The introduction of these agents followed the discovery that cholinergic neurons were depleted and that cholinergic function was significantly decreased in the basal forebrain of AD patients[3]. CSF markers of cholinergic function have been studied, but have not yielded consistent results. For example, measurements of AChE and pseudocholinesterase (PChE) have led to the conclusion that cholinergic basal forebrain neurons are not a major source of cholinesterases in the CSF and do not provide evidence for using CSF cholinesterases as a diagnostic marker of basal forebrain cholinergic cell loss[4].

The Noradrenergic System

Autopsy studies of AD brains demonstrate loss of cells in the locus coeruleus, the major nucleus of origin of noradrenergic fibres. Reduced noradrenaline (norepinephrine NE) in autopsy samples of AD brains has been a fairly consistent finding. In contrast, CSF and plasma NE and 3-methoxy-4-hydroxyphenylethylene glycol (MHPG) appear significantly higher in patients with advanced AD than in patients with moderate AD or controls[5,6]. Patients with advanced AD have not only biochemical indices of noradrenergic hyperactivity but also physiological pointers to this, including higher heart rate and blood pressure. AD patients with the most severe dementia have the greatest rise in CSF MHPG levels following administration of probenecid. There is also evidence for blunted growth hormone response to clonidine in AD patients, suggestive of altered a-2-adrenergic receptor sensitivity[7]. It may be hypothesized that increased activity and turnover of the noradrenergic system may compensate for cell loss and that a limited number of NE cells remain highly active in AD patients. Severe neuronal loss in advanced AD may lead to a compensatory increase in locus coeruleus firing rate, contributing to symptoms such as pacing, agitation, insomnia and weight loss.

The Serotonergic System

Numerous autopsy studies of AD brains have suggested a serotonergic deficit. Although there have been reports that the major serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), is unchanged in the CSF of AD patients, most studies indicate a reduction in CSF 5-HIAA. In one study that demonstrated significantly lower mean 5-HIAA levels in AD, the wide variability in values suggested that the changes were non-specific, secondary to the cerebral degeneration in AD[8]. There is also evidence of increased behavioural sensitivity to *m*-chlorophenylpiperazine in AD patients, consistent with damage to serotonin pathways[9].

Melatonin, the pineal hormone biosynthesized from serotonin, has been demonstrated to be significantly decreased in the CSF of elderly patients, and more so in AD patients. In elderly (> 80 years

of age) non-demented subjects, CSF melatonin levels were half those of younger (age 41–80) control subjects, and in AD patients the CSF melatonin levels were only one-fifth of those found in control subjects ($p < 0.0001$)[10].

Other neurochemical systems have been investigated as potential antemortem markers[11]. Somatostatin is reduced in AD brains and CSF somatostatin levels have been found to be significantly lower in patients with AD compared to controls. These findings do not, however, appear specific to AD. Other CSF peptidergic findings in AD include decreased vasopressin, decreased thyrotropin-releasing hormone, and decreased delta sleep-inducing peptide. Another system that may be disordered in AD brains comprises trophic factors such as gangliosides.

SYSTEMIC PATHOLOGY

It is possible to view AD as a systemic illness. Thus, if AD were a genetic disorder, then disturbances at the molecular level may be expressed in non-neural tissue, with systemic effects.

Studies of blood cell cholinergic function have been undertaken since central cholinergic dysfunction in AD became a favoured hypothesis. Studies of red blood cell (RBC) and plasma choline and AchE do not support their validity as antemortem markers. However, studies indicate differences in the dynamics of RBC choline uptake, suggesting a vulnerability of cholinergic neurons in patients with AD[12].

Fluidity of the platelet membrane (PMF) is increased in patients with AD compared to patients with vascular dementia (VaD) and elderly controls[1,13,14]. Only about 50% of AD patients demonstrate this abnormality; however, increased PMF appears to be a familial trait, and the subgroup of AD patients in whom it manifests suffer from an earlier onset and a more rapidly progressive decline[15]. In a prospective longitudinal study to evaluate PMF as a putative risk factor for AD, nine of 330 people with increased PMF (initially asymptomatic first-degree relatives of probands with AD) developed AD after 7.5 years[16]. On a biochemical level, it was found that free radical-induced lipid peroxidation increased the fluidity of platelet membranes, providing a postulated mechanism underlying increased PMF[17].

In fibroblasts, abnormalities in enzymatic activity, glucose metabolism, abnormal calcium metabolism, impaired DNA repair and potassium channel dysfunction[18] have been observed.

Inflammation

Neuropathological findings in AD brains show an inflammatory response. CSF interleukin-1β (IL-1β) concentrations were significantly higher in AD patients than in patients with VaD, normal pressure hydrocephalus or multiple sclerosis[19]. Activated microglia may participate in the initial stages of neurodegeneration. Microglial antibodies in the CSF have been found in AD patients[20]. CSF microglial antibodies were present in at-risk descendants of familial AD patients, some of whom subsequently developed AD, and in AD patients in contrast with other types of dementia[21]. The presence of microglial antibodies may, however, be non-specific, as a similar mechanism has been implicated in the pathophysiology of VaD. Drugs aimed at diminishing inflammation and the activity of microglia are currently being investigated.

A miscellany of other research areas in AD can conveniently be mentioned in this section. These include studies of visual system dysfunctions, olfactory deficits, extrapyramidal dysfunction, atypical dermatoglyphic patterns, altered sweat response, abnormal glucose tolerance and vitamin B_{12} deficiency. Such work, although interesting, has not yet led to a sensitive and specific antemortem marker.

Protein Abnormalities

Mutations of the amyloid β-protein precursor (APP) have been found in familial AD with early onset. A prominent feature of the senile plaques found in AD is the deposition of β-amyloid. The other hallmark lesion for AD is the neurofibrillary tangle, which contains tau protein. Given that the clinical phase of AD may be preceded by a 15–30 year period of deposition of amyloid and tau protein, markers to predict the development of AD should ultimately be obtainable[22]. While the concentration of tau protein in CSF was found to be significantly higher in AD patients compared to non-demented controls, reports of altered APP and β-amyloid CSF concentrations have not been consistent[22].

Environmental Factors in AD

Although AD has been linked to a genetic aetiology, studies with monozygotic twins revealed variability in age at onset of as much as 9, 15 or 20 years[23]. This led to the suspicion that some environmental factor(s) ingested from food and water, or a deficiency of some protective element, may accelerate disease expression in susceptible individuals. Several metals have been investigated in AD in the hope of finding a marker for the disease. Of these, iron, aluminium, zinc and mercury are considered to be the most important. Aluminium was found in neurofibrillary tangles[24,25], aluminium and silicon were found in cores of senile plaques[26] and aluminium levels were increased in the hippocampus and cerebral cortex of AD patients compared with non-demented controls[27]. Aluminium is not easily absorbed by the body, since the gastrointestial tract forms a major cellular barrier to its absorption. In AD this barrier may be compromised[28]. The findings of increased aluminium in AD have, however, been inconsistent.

Iron metabolism is altered and the iron transport protein transferrin decreased in the serum of AD patients. Furthermore, a genetic form of transferrin, TfC2, which is associated with diseases attributed to free radical damage, has an increased allele frequency in AD[29–31]. Serum levels of the iron binding protein p97 (melanotransferrin) were reported to be elevated in AD patients, discriminating between AD patients and controls[32], a finding which has to be confirmed. Finally, blood mercury levels are also significantly raised in AD patients[33].

BRAIN IMAGING

There has been considerable interest in the use of brain imaging in the diagnosis of AD (see Section EX). The medial temporal lobe is involved in cognitive functions of the brain and is the region reflecting the most extensive pathological changes in AD. Using temporal-lobe-orientated computed tomography (CT), it was demonstrated that decreased hippocampal width predicted AD with a detection rate of 92% when a cut-off was selected to yield a 5% false-positive rate. These cases were subsequently confirmed histopathologically[34]. CT scans also revealed that the atrophy of the medial temporal lobe in AD was related to the progression of pathology[35].

Magnetic resonance imaging (MRI) studies yielded similar results. On MRI, AD patients and controls were best told apart using left amygdala and entorhinal cortex volumes[36]. Coupled to blood flow studies using single photon emission computed tomography (SPECT) and using relative left temporoparietal cortex blood flow, the imaging studies yielded 100% discrimination between AD patients and controls[36]. In addition, in older patients with mild cognitive impairment, hippocampal atrophy determined by premorbid MRI-based volume measurements was

predictive of subsequent conversion to AD[37]. In distinguishing between AD and other dementias, one study differentiated AD from normal ageing, depression, VaD and other causes of cognitive impairment[38], while in another study, no significant volumetric differences were found between patients with subcortical VaD and AD patients, apart from the volume of the cerebellum[39].

Positron emission tomography (PET) has been found to differentiate between AD and VaD: in AD the typical metabolic pattern is hypometabolism in temporoparietal and frontal association areas, while in VaD scattered areas of hypometabolism extending over cortical and subcortical structures are seen[40].

CONCLUSION

It is clear that a number of difficulties beset the researcher interested in finding an antemortem marker for AD. Some of the techniques used in this search have important limitations—in particular, CSF measurements are influenced by a variety of factors. Diagnosis of AD, even at autopsy, may not always be accurate, leading to heterogeneity of the patient sample. In addition, AD may be a heterogeneous disorder, perhaps with a presenile form, but certainly with different manifestations in the much older age group. A marker may be present in a control with the AD trait who has not yet developed AD, and if a marker is related to the severity of AD, it may not distinguish between mild cases and controls. Other dementias may overlap with AD, not only in phenomenology but also in pathogenesis, and therefore display similar markers. There are also mixed cases, where patients, for example, have both AD and VaD.

Nevertheless, the work discussed here does suggest that some combination of measures may ultimately correlate strongly with biopsy diagnosis. Work in molecular and genetic biology and in brain imaging seems particularly promising and may well tie in with our knowledge of neurochemistry and neuropathology. An interdisciplinary effort to find an antemortem marker is useful not only in leading to a better delineation of AD-related dementias and AD subtypes, but also in providing a focus on central pathogenic mechanisms and their possible reversal.

Finally, markers may be expressed differently in different populations. A genetic variant of apolipoprotein E, ApoE $\varepsilon 4$ (Chapter 41) has been shown to be a risk factor for late-onset AD. Yet, in spite of relatively high frequencies of ApoE $\varepsilon 4$ in African countries, the prevalence of AD is very much lower than in the Western population[41], making it extremely important for us to understand the aetiology of the disease.

Clinical Features of Senile Dementia and Alzheimer's Disease

Brice Pitt
St Mary's Hospital, London, UK

Not all dementias in the senium are forms of Alzheimer's disease (AD), neither does AD always arise in the senium. However, the commonest form of senile dementia and of AD is senile dementia of the Alzheimer type (SDAT). In most countries this alone is thought to account for 50–60% of the senile dementias and, in a form mixed with multi-infarct dementia (MID), for another 15–20%[1].

Alois Alzheimer originally described[2] a 51 year-old woman whose morbid jealousy was followed by a rapidly progressing amnesia. She displayed paranoid delusions and, it seemed, auditory hallucinations as well as such cognitive defects as disorientation, incomprehension, perseveration, dysphasia, dysgraphia and dyspraxia. She died only 4.5 years after the onset of her disorder, when Alzheimer was enabled to make the neuropathological observations that later caused his name to be given to the disease. Thus "psychiatric" as well as cognitive symptoms were part of the syndrome from the first. Personality change and behavioural disorder are also part of the condition, especially in those referred to psychiatrists.

Most diagnostic criteria for dementia and AD, e.g. the American Psychiatric Association's *Diagnostic and Statistical Manual*, 3rd edn, Revised[3] and those of the Royal College of Physicians[4], require some degree of disability. The operational diagnostic criteria for dementia in the Cambridge Examination for Mental Disorders of the Elderly[5] include "Progressive failure in performance at work and in the common activities of everyday life—The decline in memory is sufficiently severe to impair functioning in daily life".

Presumably there must be some period of minimal impairment before the disorder becomes disabling, but it is still unclear what are the very earliest features of AD, in its senile or presenile forms. Sufferers tend not to be brought to the notice of the medical or social services until problems arise that jeopardize self-care or strain relationships, when the disease has usually been developing for at least 2 years. Epidemiological surveys using such screening instruments as the Mini-Mental State Examination[6] have, however, identified some people with mild or borderline cognitive impairment, as have the memory clinics which have been developed in recent years[7], and some of these have been shown later to have developed dementia. The distinction between those suffering from Kral's[8] "benign senescent forgetfulness" (BSF) or Crook's[9] "age-associated memory impairment" (AAMI), both of which advance very gradually, if at all, and early AD is not very clear. In a Cambridge field study[10] about half of those with mild memory impairment later developed dementia, but it would have been hard to predict which. Among BSF subjects at the Maudsley Memory Clinic[11], however, there was a tendency for men and those whose forgetfulness was noticed by others subsequently to develop dementia.

ORGANIC DISORDERS

The start of AD is usually manifest in memory impairment:

1. Things are mislaid at home, cannot be found in their once familiar places, or are left behind at home, in shops or in cars, buses and trains.
2. There is an increasing need to check that things have been done and reliance on aides-memoires; even so, appointments and plans are forgotten.
3. The same remarks are made and the same questions asked again and again, and conversation rambles on irrelevantly.
4. Recent information and activities are forgotten and messages are not passed on.
5. The start of a story is forgotten before it is over, so it is difficult to follow plays, films, books or news.
6. New locations, as when on holiday, are not learnt easily, and the patient may get lost.
7. Some things may be done twice over, like feeding an animal or cleaning teeth, and others not at all, like paying bills or taking needed medication for, say, heart-failure or diabetes.

At a later stage:

8. Once-familiar faces and places and locations seem less familiar, and eventually the sufferer may be lost in his/her own neighbourhood or even in his/her own dwelling.
9. The nearest and dearest may not be recognized, and treated as strangers, while true strangers may be greeted warmly as old friends or family.
10. The day, and the time of the day, are forgotten, and the patient may go shopping in the middle of the night, and be unable to find his/her own home on returning.
11. Sometimes the patient no longer knows his/her age or birthday, or that his/her parents are no longer alive, and has indeed entered upon a "second childhood".

Language impairment is usually regarded as a later feature of AD[12]. The sequence of deterioration begins with tasks, such as naming, which use the semantic system, concerned with the meaning of words. There follow deviations and simplifications of syntax (grammar), and then phonemic breakdown (disordered use of sounds)[13]. One study[14] found more deficits on the Boston Naming Test than the Mini-Mental State Examination in early

dementia, suggesting that naming difficulties may precede memory failure. Whether the common difficulty in finding proper names experienced by the over-50s[15] is related to the later onset of dementia, or is merely a manifestation of "AAMI", has yet to be determined. Perseveration in AD is much less common than confabulation. Difficulties in understanding, as well as in finding, some words increase during the dementia, until finally there is almost total incomprehension and incoherence. Difficulties in reading and writing may precede those affecting the spoken word.

Loss of intellect is traditionally demonstrated by psychometric tests, which show a greater impairment of "performance" than "verbal" IQ[16]. It is also exposed by difficulty in defining concepts and explaining similarities in the course of cognitive testing. In everyday life it is mainly manifest in illogical thinking and often inconsistencies, e.g. "I live with my mother". "How old is she?" "Oh, in her 80s". "But how old are you?" "I'm 82". "Then you're about the same age as your mother?" "That's right!" There is a failure to draw appropriate deductions from environmental cues: a shopping expedition is undertaken in pitch dark, or, despite the blizzard evident outside the window the season is stated to be summer. A lack of "common sense" contributes to the increasing dependency.

Judgement and creativity are early casualties of dementia, and a good sense of humour may be the first loss. Taste in music, art, reading, clothing and decor may be coarsened, so that the patient wears a garish or incongruous garment, comes back from the shops with a tatty ornament which clashes with the fastidiously appointed living-room, only reads familiar books or gives up *The Times* for a tabloid newspaper. Exploitation by unscrupulous callers, who offer a few pounds for valuable heirlooms, is all too easy. Wills are changed without due regard for those who might have expected to inherit, in favour of some *parvenu* opportunist, causing deep hurt, disappointment and disputation when the patient has died. Judges and physicians become erratic and unreliable and artistic activity ceases or becomes facile, empty and repetitive.

Agnosia contributes, with amnesia, to disorientation. A failure of recognition of faces (prosopagnosia), places and objects bewilders the patient and his/her carers. Apraxia presents as difficulties in dressing—clothes are put on, if at all, in the wrong order, back to front and upside down—and feeding: knife and fork may have to be replaced by a spoon, and the patient may then use his/her hands or lap food from the plate. Apraxia may affect walking, when there is difficulty in judging the height of steps, or a change in the covering or the colour of the floor may be perceived as a step.

A personality change is not inevitable in AD, neither is it always for the worse. Occasionally, those who recognize their limitations and the need for others' help become less dominant and assertive and more docile, mellow and biddable. Commonly, however, as the dementia progresses the range of responses narrows, animation and spontaneity are subdued into apathy and indifference; the unpleasant label "vegetable-like" can apply. Some people become uncharacteristically coarse and disinhibited, swearing and using obscenities. There may be frequent, noisy, seemingly insatiable demands. Irritability, reproaches and angry outbursts can devastate and mystify carers. Regression in dementia facilitates the crude use of mental mechanisms, notably denial and projection: problems are denied or blamed on others. "There's nothing wrong with my memory—why, I can remember years back. It's other people who muddle me up by trying to catch me out. If they'd just leave me alone I'd be all right". A loss of insight, however, is not inevitable in AD, or not until loss of language prevents its expression. Alzheimer's original patient sometimes declared that she could not understand anything, and many sufferers are similarly painfully aware that there is something terribly wrong with their health.

Disordered behaviour is often the most distressing and challenging aspect of progressive AD[17]. Behavioural and psychological symptoms of dementia (BPSD) are strong predictors of caregiver burden and psychiatric morbidity[18]. Some forms arise understandably from personality change and cognitive deficits, while others might be core features of the dementia[19]. Studies based on those patients or clients referred to health and social services are likely to find disordered behaviour more often than in those who manage or are managed without such help at home, although few epidemiological studies assess behaviour as well as cognitive deficits. O'Connor *et al.*[20] found that among community residents in Cambridge, UK, such disturbed behaviour as demanding attention, repeating questions, using bad language, noisiness, temper outbursts, physical aggression and nocturnal wandering increased with the severity of dementia: 7% of those with mild disorder were aggressive and 42% of the severely demented.

Withdrawal and reclusiveness can have a protective function for those who find that the complexities of their former life are now beyond them. Self-neglect and squalor may be the inevitable consequence of incompetence and lack of help, often because it is refused, although sometimes demented people who live with others are reluctant to wash themselves or to change their clothes when it is time they did. Hoarding and clutter may result because of difficulty in taking the decision to throw rubbish away. Leaving the gas on, carelessness with cookers and inadvertent fire-raising are simple, although dangerous, consequences of forgetfulness and impaired judgement. Verbal abuse and acts of aggression are consistent (although still alarming) with explosive irritability, and the "catastrophic reaction" to exposure of cognitive incompetence in those who robustly deny it makes some sense, both as a form of protest and as a defence. Disinhibition—social, being excessively outspoken, tactless, fulsome or critical, yawning and nodding off during a conversation or a meal and departing from a gathering prematurely and abruptly; minor shoplifting (although this may be partly due to dysmnesia); and, occasionally, sexual disinhibition, taking the form of stripping, exposure, open masturbation and importuning—cause carers and companions various degrees of embarrassment and shame. Noisiness may be associated with boredom, deafness, the desire for attention or depression (see below). Interfering with appliances and destructiveness may be a perverted form of "do-it-yourself"! Strange actions like talking to the reflection in the mirror as if it were another person and to photographs as if they were real people may be partly attributable to prosopagnosia.

Wandering and incontinence, two of the most troublesome behaviour disorders, are often overdetermined. Wandering may arise from utter boredom and underactivity; it is difficult to interest someone who can no longer read or enjoy television or radio and who is discouraged from going out alone for a walk or to the shops, lest they should get lost. Wanderers might have been in the habit of taking a walk with the dog or to buy cigarettes or a paper, at that time of day. They may be seeking their home even if actually at home; it may not be recognized as such, and there is a vain, vague, poorly (if at all) articulated quest for the home where they used to live. Wandering is sometimes a sign of agitated depression (see below) and occasionally a wanderer may be trying to get away from a loaded bowel! Restlessness towards nightfall ("sundowning") and nocturnal roaming[21] by patients who have no idea of the time and are bored as well as restless, are a particular strain on carers[22].

Incontinence of urine may occur for other reasons than dementia—stress incontinence, the frequency of a urinary tract infection, polyuria from diabetes or a prescribed diuretic. The foresight to urinate when the chance arises may have been lost, the location of the lavatory forgotten, or a vaguely similar place (like a cupboard or a storeroom) used in its stead. In advanced dementia

the patient may not appear to care any more where he/she excretes; alternatively, cortical control of the bladder may have been lost. Incontinence of faeces may be associated with impaction, compounded by poor hygiene, resulting in soiling and smearing[23].

The psychiatric features of the disease, described first by Alzheimer[2] and reaffirmed recently by Berrios and Brook[24,25] and Burns and colleagues[26–29], include affective disorder, paranoid and other delusional states and hallucinations. The affect in the disease is often blunted or labile, but it is now apparent that, at least among those seen by psychiatrists, depressive symptoms are common—63% of the 178 patients in Burns' series[28] having at least one. Depression was associated with less cognitive impairment, suggesting that it was related to insight. As most demented patients cannot describe how they feel, the Cornell Scale for Depression in Dementia[30] combines observed and informant-based signs of such possible depressive phenomena as diurnal variation, anorexia, insomnia, agitation and retardation and lack of engagement in activities, as well as overt misery.

Paranoid delusions of theft and intruders are a not uncommon reaction to losing things and are an example of projection. Such accusations are grievous to a loyal carer, as are those arising from morbid jealousy. Capgras' syndrome[31], in which it is claimed that a stranger has adopted the appearance of someone well known to the patient, is rare but intriguing. Sixteen per cent of those in Burns' series[26], and 37% of those in Berrios and Brook's[25] were deluded.

Visual hallucinations tend to occur towards nightfall, and often take the form of little people—children, dwarfs or Lilliputians—who have to be fed. This is one reason why demented people may prepare meals for a household of people when only one or two are needed (another being because they have forgotten that their children have grown up and left home, as in Margaret Forster's moving novel *Have the Men Had Enough?*[32]. Sometimes the very small people seem to emanate from a television set, which may act as a hallucinogen[33]. Visual hallucinations are more common when the eyesight is impaired, and may be symptomatic of sub-acute delirium, superimposed on the dementia. Burns[27] found that 13% of his series of patients had visual hallucinations, and 10% auditory, but in clinical practice the latter are of little or no importance.

Finally, there are a number of neurophysical and other disorders associated with AD, including (towards the end of the illness) parkinsonism[34], gait apraxia[35], fits[36] and primitive reflexes[37,38]. Weight loss in AD is particularly interesting, and not solely explicable by inadequate diet because of reluctance or forgetting to eat or to overactivity[39].

The course of AD is one of progressive deterioration from its insidious onset until death, 1–20 years later. Although younger patients live longer, they show the highest excess mortality[40]. Measures of deterioration, like the Global Deterioration Scale[41], rely upon a more uniform progression than is always found. Plateaux, when the clinical disorder seems for a while to be stationary, are not inconsistent with the diagnosis of AD[42]. Early language deficits[43] carry a poor prognosis for survival. Bondareff[44] postulated two forms of the disease: AD1, in older subjects, with a gradual course, mainly affecting memory; and AD2, in younger people, affecting temporoparietal functions and running a relatively rapid course. The two forms are also distinguished by their neuropathology and the pattern of neurobiochemical abnormalities. Death, when sooner or later it comes, is commonly from bronchopneumonia[45], developing in a person who by now is very helpless (often requiring to be fed) and debilitated.

Assessment and Management of Behavioural and Psychological Symptoms of Dementia (BPSD)

Rupert McShane[1] and Niall Gormley[2]

[1]*Warneford Hospital, Oxford, and* [2]*Institute of Psychiatry, London, UK*

ASSESSMENT

The evaluation of BPSD should include: (a) a clear description of the target behaviour, including its antecedents and consequences ("ABC" behaviour analysis); (b) a search for external (e.g. physical environment, carer behaviour), physical (e.g. pain, delirium) and mental (e.g. psychosis) precipitating factors; and (c) an assessment of the risks posed by this behaviour to the patient, carer or other residents.

One good way to understand how to assess the range of BPSD is to use one of the many scales that have been developed[1,2]. These tend to have a number of features in common. First, the principal carer should be the main source of information about the patient's behaviour. Second, the frequency of the phenomenon in question may be a more useful question than "how severe is the problem?", since the latter is more subjective. Third, the time frame should be specified—usually a month or a week.

The term "agitation" is widely used in research and clinical practice but has been used to denote restlessness or aggression or mood changes, each of which should be individually described when analysing the "agitated" patient. "Psychosis" should similarly be dissected into component phenomena: visual and auditory hallucinations, delusions and misidentifications of various types. The issue of which symptoms tend to co-occur is controversial but important, since such clusters may reflect distinct underlying aetiologies[3].

MANAGEMENT

Until recently, there were few good quality trials of treatments for BPSD. This is in part because such trials are difficult to do. Patients are by definition most unlikely to be able to give consent to participate, "BPSD" are heterogeneous and staff are often reluctant to risk stopping medication, believing that they may be making patients easier to manage[4]. In trials of pharmacological interventions, "escape" or "rescue" medication (usually chloral or lorazepam) is needed. Nevertheless, the recognition of the burden these symptoms place on carers and of their tendency to result in the breakdown of caregiving in the home, coupled with the increasing evidence of harmful effects of conventional neuroleptics, has driven a fast-moving field.

Non-pharmacological Management

> I consider the direct treatment by mere medicinal applications to be very limited. A kind and soothing reception, immediate removal of restraints, a warm bath, clean clothing, comfortable food, encouraging words, a medical treatment first directed to any manifest disease... A liberal diet, moderate use of malt liquor, exercise out of doors, employment, recreation, mental occupation, friendly intercourse and judicious religious attentions, are all important auxiliaries to amendment.

John Conolly, who was Medical Superintendent at Hanwell Asylum when he wrote this in 1847, was not writing specifically about dementia. However, there is no doubt that, overall, the management of BPSD requires more attention to psychosocial factors and to physical illness than to psychiatric factors. A variety of general supportive measures and specific behavioural interventions have been used.

General Measures

Dementia therapies. Reality orientation, reminiscence therapy and validation therapy are the best-known examples of therapies developed for use with elderly people. Although these interventions may provide valuable stimulation and foster therapeutic optimism, there is little evidence to suggest that they produce significant or sustained improvements in behaviour problems.

Stimulation-orientated therapies. Inadequate stimulation appears to have a negative impact on cognitively impaired elderly people. Training carers to identify and increase the number of pleasant activities for their dependants improves depressive symptoms[5]. Musical stimulation reduces disruptive vocalization in some patients[6]. For nursing-home residents, therapeutic activity programmes, as well as the physical environment, are important sources of stimulation. Rovner *et al.*[7] found that a programme which included music, exercise and crafts, combined with guidelines on the use of psychotropic medication, reduced the prevalence of behavioural disorders and antipsychotic drug use. In one of the few environmental studies, Cohen-Mansfield and Werner[8] found that simulating a home or natural outdoor environment within a nursing home using visual, auditory and

olfactory stimuli resulted in a modest reduction in pacing and other agitated behaviours.

Behavioural Interventions

Behavioural models, most commonly based on operant learning theory, have been used to design interventions for specific behavioural problems in dementia. An "ABC" analysis may suggest the implementation of specific behavioural techniques, including: (a) antecedent control—modification of events which trigger disruptive behaviour; (b) extinction—target behaviour is discouraged when it is not rewarded; (c) differential reinforcement of other behaviour (DRO)—the provision of positive reinforcement only for behaviours incompatible with the problem behaviour.

Personal care, for example, is a common antecedent to aggressive behaviour. This may occur because an intrusion into a patient's personal space is misinterpreted as a threat. In such circumstances, careful prompting by the carer, an adequate explanation of the procedure and simple one-step instructions may reduce the perception of threat, and subsequently eliminate or reduce the defensive response. Similarly, if a nursing home resident's only input from staff occurred following verbal outbursts, the staff response might serve to reinforce the behavioural problem. A behavioural analysis would allow staff to modify the antecedent (inactivity), or their own responses, through the use of extinction or DRO.

What is the evidence for the efficacy of behavioural interventions in dementia? Teri *et al.*[9] have found that family carers can learn behavioural management strategies and that these interventions can reduce a wide variety of behavioural problems. In a controlled trial of a comprehensive carer training programme, which focused on behaviour management training and family support, carers' negative reactions to behavioural problems were reduced, even though there was no reduction in the incidence of disruptive behaviours[10]. The majority of studies evaluating behavioural interventions in agitated nursing home residents have reported favourable results, mainly through the use of antecedent control and reinforcement of positive behaviours[11].

However, two larger recent studies failed to find a significant effect of behaviour management programmes[12,13].

Conclusion

Although psychosical interventions have been shown to reduce behavioural disturbances, significant obstacles exist to their widespread implementation. There has been insufficient evaluation of clearly defined strategies targeted at specific behavioural problems. Therapeutic gains, in many cases, persist only for the duration of the intervention. In addition, staff compliance with behavioural strategies is often poor, perhaps unsurprising when their inadequate training and poor working conditions are taken into consideration. The successful implementation of psychosocial interventions in dementia requires the continuing support and training of professional and family caregivers.

Pharmacological Interventions

In this chapter, recent randomized studies are summarized and the effect of different drugs on clinically important measures is compared using "numbers needed to treat" [NNT = 1/(difference in proportion responding to each treatment)]. The lack of a consistently applied definition of "clinically important measures" can limit the validity of such comparisons, particularly when using data from meta-analyses[14]. Nevertheless, NNTs and NNHs (numbers needed to harm) are powerful and simple ways of expressing clinically meaningful information, and are the best statistics available for making comparisons[15]. An NNT of less than 5 on a clinically important variable would usually indicate a drug that clinicians would find very useful.

"Typical" neuroleptics

Three meta-analyses have considered the efficacy of typical neuroleptics. In the first, Schneider[16] showed an 18% difference between placebo and active drug in the proportion of patients responding to drug and placebo, equivalent to an NNT of 5.6. A more detailed presentation of 16 randomized trials since 1966 found an overall NNT for "improvement" on neuroleptics of 3.8 and an NNH of 4.0[17].

Thioridazone. The Cochrane meta-analysis of the effect of thioridazine in dementia[18] found only one large placebo-controlled study that reached inclusion criteria[19]. This was a multicentre study of 610 institutionalized patients in which 4 weeks of thioridazine was compared to placebo and diazepam. Thioridazine improved the "anxiety/tension/fears/insomnia" factor of the Hamilton Anxiety Scale with an NNT of 2.6, and the "cognitive impairment/agitation/depressed mood/behavioural change" factor with an NNT of 3.1. However, the overall conclusion of the Cochrane authors was that, because of the poor quality of reporting of trials: "If thioridazine were not currently in widespread clinical use, there would be inadequate evidence to support its introduction . . . [It] has minimal or no effect on global ratings, while other drugs such as chlormethiazole are superior to it on behavioural ratings".

Haloperidol. Devanand and colleagues[20] (1999) addressed the question of optimal dosing of haloperidol. This was a study of 71 outpatients with Alzheimer's disease with a mean Mini Mental State Examination (MMSE) of 10. The majority of patients showed both psychosis and disruptive behaviours, so it was not possible to tease out any differential effect on the two classes of disorder. Response rates according to three sets of criteria were greater with the standard dose of 2–3 mg daily (NNT 3.3–4.0) than with low dose (0.5–0.75 mg). A subgroup (20%) of those on 2–3 mg daily developed moderate to severe extrapyramidal signs (NNH = 5), but did not meet consensus criteria for dementia with Lewy bodies. The authors recommend a starting dose of 1 mg/day with upward titration.

Atypical Neuroleptics

Risperidone. The largest good quality trial to date of drug treatment for BPSD has been that of Katz *et al.*[21]. Nursing home residents with dementia were treated for 12 weeks with either 0.5 mg, 1 mg or 2 mg risperidone daily, or placebo (approximately 150 in each arm of the study). Most had severe dementia: the mean MMSE was 6.6. The primary outcome measure was a 50% reduction in the BEHAVE-AD, which occurred in 33% taking placebo, 45% on 1 mg (NNT = 8.3) and 50% on 2 mg (NNT = 5.9). Interestingly, risperidone appeared to have an anti-aggression effect (NNT = 3.4–3.9) that was independent of its effect on psychosis (NNT for delusions 7.1 at 1 mg, 10.0 at 2 mg) or its tendency to cause somnolence. The dropout rate varied from 27% in the placebo group to 42% in the 2 mg group. The NNH for sedation was 11.2 for the 1 mg dose and 5.0 for the 2 mg dose. Extrapyramidalism was more common at 2 mg (NNH = 7.2) than at 1 mg (NNH = 18.5). The optimal dose of risperidone is therefore 1 mg daily.

Olanzapine. Street *et al.*[22] studied 206 nursing home patients with a mean MMSE of 7.3 in a trial of six weeks of olanzapine or placebo. The main outcome measure was a 50% reduction in the Neuropsychiatric Inventory (NPI) score for a newly defined cluster of symptoms (hallucinations, delusions, agitation). The optimal dose (5 mg) was as effective as typical neuroleptic (NNT = 3.3) but seemed to be associated with relatively high rates of adverse reactions. The response rates (66% on 5 mg, 52% on 10 mg, 43% on 15 mg and 36% on placebo) suggest that doses higher than 5 mg are likely to be suboptimal. Somnolence and gait abnormality were the commonest side effects (NNH = 5.4 and 5.7, respectively) This study illustrates the difficulties that occur in comparing adverse drug reactions (ADRs) across studies, since it is very likely that ADRs were more assiduously sought in this study than earlier studies of typical neuroleptics. The lower dose of 2.5 mg, which is now available—and which one would expect to be associated with fewer ADRs than 5 mg—was not tested.

Carbamazepine. Few trials have published significant differences in responder rates on measures of Global Clinical Impression (CGI). One exception is the study of Tariot *et al.*[23]. At least minimal improvement on the CGI was apparent in 77% of those taking carbamazepine compared to 22% on placebo (NNT = 1.8). Furthermore, the reduction in the number of cases requiring "a great deal" or "almost constant" extra nursing time to deal with the agitation was 37% in those taking carbamazepine and 8% in those taking placebo (NNT = 3.4). This was a relatively small (ca. 25 subjects in each arm) 6 week study of predominantly female nursing home residents with severe dementia (mean MMSE 6.0), 92% of whom were aggressive. Carbamazepine was started at 100 mg/day. The modal dose reached was 300 mg/day. The NNH for any ADR was 3.3, although these were considered clinically significant in only 2 of 16 cases. The large effect size may have been at least partly attributable to the fact that a non-blind physician adjusted the dose of carbamazepine—a strategy which, of course, parallels the clinical situation, but is not commonly employed in more recent studies.

Trazodone. Trazodone is widely used for BPSD, although there has only been a single small randomized trial of its effectiveness, in which it was shown to be comparable in effect to haloperidol[24]. The CGI was "much improved" or "very much improved" at week 9 in 57% of cases on haloperidol and 71% on trazodone. However, trazodone was associated with fewer side effects (14%, mean dose 218 mg) than haloperidol (50%, mean dose 2.5 mg). Interestingly, post hoc analyses suggested that those who were verbally aggressive or had repeated behaviours or mannerisms were more likely to respond to trazodone. Those who paced, were generally restless or made unwarranted accusations were more likely to respond to haloperidol. This raises the possibility of two syndromes of behavioural change in dementia, one associated with abnormalities of dopaminergic function and one associated with serotonergic dysfunction. The replicated finding that those with depression early in dementia are more likely to go on to be physically aggressive is also consistent with the possibility that there is a distinct serotonergic syndrome of behavioural change in dementia[25,26]. It is not necessary for other signs of depression to be present to justify a trial of an antidepressant for aggressive behaviour.

Xanomeline. Xanomeline is a cholinomimetic with agonist activity at postsynaptic muscarinic M1 and M4 receptors. Bodick *et al.*[27] presented data from a large (87 in each arm), 6 month study of patients with mild to moderate AD. Three doses of xanomeline were compared with placebo. The dropout rate was high, ranging from 35% in the placebo group to 59% at the highest dose of active drug (NNH = 4.2), precluding its further use in the formulation used. However, there was a dose-related response to xanomeline of hallucinations (NNT = 2.1 at the highest dose) and a variety of other behaviours (e.g. vocal outbursts, delusions and mood swings; NNT = 2.7–6.4).

Rivastigmine. The cholinergic nucleus basalis of Meynert is in double jeopardy in patients with dementia with Lewy bodies (DLB) because it is likely to degenerate as a result of both Lewy body and neurofibrillary change. Cortical cholinergic parameters show even more marked depletion in DLB than in AD. There is now evidence showing that patients with DLB are preferential responders to cholinesterase inhibitors. McKeith *et al.*[28] conducted a 20 week placebo-controlled study of 3–12 mg rivastigmine in 120 patients with probable or possible DLB of mild to moderate severity. The main outcome measure was a 30% reduction on a newly defined cluster of symptoms derived from the NPI: hallucinations, delusions, depression and apathy. A 30% reduction was chosen because it was comparable to the effect size seen with neuroleptics. The main result was based on the observed case analysis: 63% of those on rivastigmine responded, compared to 30% on placebo (NNT = 3.0). Although there was no overall difference in the number of ADRs (59 vs. 61%), those taking rivastigmine were significantly more likely to drop out (31% vs. 16%; NNH = 7.1). As well as improvements in the pre-defined cluster, there were also marked improvements in a computer test of attention in those on rivastigmine.

These two studies provide good evidence that hallucinations in particular, and possibly other BPSD, respond well to cholinergic agonism.

When to Consider a Trial without Medication

Neuroleptics have unpleasant side effects. Sedation, falls, hip fractures and tardive dyskinesia are common sequelae. Indeed, the prescription of typical, rather than atypical, neuroleptics is likely to be a false economy, particularly if there is any risk that the drug will be taken for more than a brief period. Trials without neuroleptics are a legal requirement in nursing homes in the USA, following the OBRA-1987 regulations. What is the optimal duration of treatment before a trial without medication is indicated?

Since evanescent symptoms do not require long periods of treatment, an important related question is "How often would the symptom normally be expected to resolve without drug treatment within a given time?" Levy *et al.*[29] assessed 181 outpatients and found that 60–70% of those with agitation or psychosis still had the symptom 3 months later. Persistence was more common amongst those with low MMSE scores (12–17). Devanand *et al.*[30] in an outpatient study of 235 patients with early AD, found that 74% of those with wandering or agitation had the symptom 6 months later. Comparable figures for other behaviours were: physical aggression 53%, hallucinations 52%, paranoid ideas 45%, misidentification 56%. In a group of 48 patients with autopsy-confirmed AD, Hope *et al.*[31] found that aggression and hyperactivity were both still present in 75% of cases after 8 months, and hallucinations were still present in 75% of cases at 11 months. All these studies were potentially directly or indirectly confounded by the effect of psychotropics on the natural history of behaviour. Nevertheless, these data suggest that BPSD may endure for up to 8 months in approximately 75% of cases and be evanescent in 25%.

How often will trials without treatment succeed and how often will they fail? Cohen-Mansfield *et al.*[4] studied the effect of withdrawal of drugs from nursing home residents, many of whom will have had dementia. The doses of haloperidol (mean = 0.9–1.3 mg), thioridazine (25–27 mg) and lorazepam (0.7–0.9 mg) that were being used were within current standards of care. The design

was a cross-over study with 6 weeks in the drug or placebo arm. Of 194 residents who were taking regular medication at the start of the study, only 58 (30%) participated, but only 16 (8%) cases were excluded for reasons that potentially related to their behaviour. Thirty-five (60%) completed the study. Dropouts due to emergence of BPSD were not more significantly likely to occur in the withdrawal phase (six cases) than the continuation phase (three cases). After correction for multiple comparisons, BPSD were not more likely to re-emerge following drug withdrawal than with continuation. There was also a slight improvement in cognitive function. At face value, this study suggests that a trial without medication at 6 weeks is indicated. However, the difficulty of sustaining non-pharmacological approaches to the management of BPSD in nursing homes was shown by the fact that, during the 22 weeks following discontinuation of the original drug, less than one-third of cases remained free of psychotropic medication. The mean time until receiving another psychotropic drug was 21 days.

SUMMARY

Old age psychiatrists are often called for advice when psychosocial interventions have been tried and have failed, or the resources of the staff to try such interventions are limited. Careful judgement is needed in these circumstances, since a decision not to prescribe can make a precarious situation worse. Drug treatment can provide a breathing space during which "something" has been seen to be done, as well as having a useful "real" impact in the 75% of cases in which the behaviour persists. The relatively high placebo effect (often 30–40%) can be useful, as long as the maxim '*primum non nocere*" is borne in mind. It is important not to leave patients on medication without having a trial of drug withdrawal. Recent demonstrations of the efficacy of atypicals, carbamazepine, antidepressants and cholinomimetics are important evidence that this most neglected area of psychiatry need not be dominated by therapeutic nihilism. Brief programmes of behavioural management are probably only effective briefly, if at all. Continuing support and training are required for successful psychosocial interventions.

Eating Disorders in Alzheimer's Disease

Paul E. Cullen[1] and Clive Ballard[2]

[1]*Bushey Fields Hospital, Dudley, and* [2]*Newcastle upon Tyne General Hospital, UK*

Eating disorders are a recognized feature of dementia, which include a preference for sweet foods (11%), increased (21%) or decreased (22%) consumption and eating non-food substances (3%) and are particularly common in Alzheimer's disease (AD)[1]. Clinical[1] and subclinical[3] swallowing problems, general dental health and oropharyngooesophageal function are all important. The basic necessity of eating to maintain health, the frustration that disordered eating causes to caregivers and the increased risk of institutionalization and death all make this an important topic[4].

A number of rating scales to evaluate psychopathology in dementia now include an eating disorder subcategory (e.g. Neuropsychiatric Inventory), whilst other scales have been developed specifically to assess eating disorders in AD[5].

Several neurotransmitters have been linked to eating disorders in AD. Reduced neuropetide Y and norepinephrine are associated with anorexia, whilst the action of galanin in the hypothalamus is thought to increase fat intake and impact upon cholinergic hippocampal systems.

Studies have shown associations between specific brain changes and eating disorders in AD, e.g. hyperorality with widening of the third ventricle and frontal and occipital lobe atrophy, Klüver–Bucy syndrome features with temporal lobe atrophy[14] and low body weight with temporal cortical atrophy[6]. Hyperphagia may be associated with increased calorific need in patients with motor restlessness, whilst younger people with more severe dementia who are not restless may over-eat because they respond to any food stimulus, possibly as a manifestation of frontal lobe pathology[7]. The European Commission has focused upon weight loss in AD[4].

In practice there is little evidence to inform the management of these problems. The best approaches generally involve common sense and clinical judgement. The most frequent clinically significant problems relate to poor appetite and weight loss. A first step is to assess and treat underlying disorders. This may vary from assessment of oral health to the pharmacological treatment of a concurrent depression. Educating care staff and informal carers about some of the changes in food preference and encouraging flexibility with the content and timing of an individual's diet is often an effective remedy[8–10].

Giving a diet with a higher proportion of sweet foods, such as desserts, chocolate, cakes and biscuits, is a pragmatic approach. This is helpful as it takes pressure off carers to produce a strictly balanced diet of cooked dinners, which eases the stress of mealtimes. Other types of difficulty are less frequent, and are probably best treated after a detailed individual evaluation, using techniques such as an Antecedent–Behaviour–Consequence ("ABC") diary. Work pertaining to ideational apraxia[11] and attribution theory[12] has contributed to the management of these problems. The management of eating disorders in AD raises important ethical issues[13].

Pathology of Vascular Dementia

J. M. MacKenzie
Grampian University Hospitals NHS Trust, Aberdeen, UK

Cerebrovascular disease is usually considered to be the second commonest cause of dementia, although the precise prevalence and the frequency of combination with Alzheimer's disease (AD) is very variable. In the West, approximately 15% of autopsy-studied cases of dementia have been attributed to vascular disease alone and 8–18% to a combination of vascular disease and AD[1,2]. However, this has been challenged in a recent autopsy study of patients in a dementia clinic, where dementia could not be attributed in any case to vascular disease alone[3]. Vascular dementia is commoner in the Far East than in the West and still remains the commonest form of dementia in Japan[4]. In the West, it may also be commoner than AD in the very elderly[5]. Estimates based on death certification and clinical diagnosis without pathological confirmation are liable to be significantly inaccurate[6,7].

If it is difficult to determine how frequent vascular dementia is, it is also difficult to define what it is. For example, the terms "arteriosclerotic" and "multi-infarct" dementia are often used synonymously and these, together with a lacunar state and Binswanger's disease, have been grouped together[8]. In practice, three separate forms of vascular dementia can be identified, although there is often overlap between these: multi-infarct dementia; dementia due to single strategically-placed infarcts; and dementia due to diffuse white matter damage[9].

MULTI-INFARCT DEMENTIA

Multiple areas of infarction involving both cortical and subcortical locations, separated in both time and space, may be associated with dementia, although in its pure form this is probably uncommon[10]. The location of the infarcts is probably more important than the volume of tissue lost (100 ml is the oft-quoted figure)[1,11]. Dementia may occur with relatively little tissue loss, particularly if infarcts are strategically located (see below) and the effect of subsequent infarcts may be synergistic rather than additive[12].

Multiple small infarcts of deep white matter or grey structures ("lacunar state") may also be associated with dementia, although this often overlaps with dementia due to diffuse white matter damage[13]. Patients with a pure lacunar syndrome show features of a subcortical dementia—psychomotor slowing, poor concentration, indecision and apathy—without features of cortical dysfunction[9]. Hypertension is the most important risk factor for dementia of this kind and that is particularly true for dementia due to multiple lacunar infarcts[13,14].

DEMENTIA DUE TO SINGLE STRATEGICALLY PLACED INFARCTS

Dementia may result from single infarcts involving certain areas of the brain, such as the angular gyrus of the dominant parietal lobe, the medial thalamic nuclei and head of the caudate nucleus, especially if bilateral, the globus pallidus, basal forebrain and hippocampus[9,15]. The cognitive effects of infarction of the angular gyrus may closely resemble AD, although the sudden onset of the cognitive deficit may point to the correct diagnosis[16].

DEMENTIA DUE TO DIFFUSE WHITE MATTER DAMAGE

Whilst white matter damage due to multiple infarcts may be the substrate of dementia, there are also forms of more diffuse white matter damage due to small-vessel disease which result in dementia, and these are probably commoner than dementia due to single or multiple infarcts[17].

Binswanger's disease is considered to be a well-established clinicopathological entity: ischaemic periventricular leukoencephalopathy manifested clinically by subcortical frontal executive dysfunction, parkinsonism, urinary incontinence, mood changes and pseudobulbar palsy[18]. However, it is still the subject of considerable controversy regarding both its frequency[19] and its relationship with the radiological entity of "leukoaraiosis"—the appearance of low attenuation areas in the white matter on CT scanning[20]. CT abnormalities are common in the elderly and may not be associated with dementia[21,22] and the clinical significance of leukoaraiosis remains incompletely defined[23]. It certainly does not equate to Binswanger's disease, despite suggestions to the contrary[24].

A review of the pathological features of all the reported cases of Binswanger's disease in the world literature, 1912–1986, together with Fisher's review, reveals that the vast majority of cases designated as Binswanger's disease show consistent pathological changes[25,26]. The general autopsy shows evidence of prolonged systemic hypertension. The brain is of average weight but there is diffuse dilatation of the lateral and third ventricles, with rarefaction, discoloration and a rubbery texture of the periventricular white matter, particularly in the occipital regions. The arteries of the Circle of Willis are affected by atheroma, which in 60% of cases is severe. Lacunar infarcts are usually present but one-third of brains also contain large infarcts. Microscopically, there is incomplete diffuse demyelination, with gliosis and microinfarcts affecting the periventricular white matter but sparing the subcortical fibres, corpus callosum, anterior

commissure and internal capsules. The walls of white matter penetrating arteries are hyalinized but the vessels are patent. This condition is probably caused by hypoxic–ischaemic damage to the distal watershed periventricular white matter, secondary to narrowing of arterioles[23,27,28].

A closely related cause of dementia due to diffuse white matter damage is CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy)[29]. This is a disease that usually presents in the fifth decade with strokes or dementia, and is an inherited vascular disorder due to mutation affecting the *Notch3* gene on chromosome 19. Pathologically, the disease is very similar to Binswanger's disease, with widespread lacunar infarcts and diffuse cerebral white matter degeneration. The distinguishing feature is the presence of non-hypertensive arteriolosclerosis, characterized by deposition of granular osmiophilic material in relation to vascular smooth muscle cells, with degeneration of these cells and thickening of the vessel walls. This is a systemic vascular disorder, although other tissues are less severely affected than the brain, and the diagnosis is therefore possible on skin or muscle biopsy, although genetic analysis is required for confirmation[30].

In the experience of the author, vascular dementia is much less common than AD. However, it is given a significance disproportionate to its incidence by the fact that some causes of vascular dementia—such as giant-cell arteritis[31] and thromboangiitis obliterans[32]—are potentially treatable, and that vascular dementia as a whole is theoretically preventable by addressing risk factors for cerebrovascular disease[33].

International Criteria for Vascular Dementia and Their Problems: ICD-10, DSM-IV, ADDTC and NINDS-AIREN

John V. Bowler[1] **and V. Hachinski**[2]
[1]*Royal Free Hospital, London, UK and* [2]*University of Western Ontario, London, Canada*

There are two sets of criteria currently available for the diagnosis of vascular dementia. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn (DSM-IV)[1] and the *Classification of Mental and Behavioural Disorders*, 10th Revision (ICD-10)[2] are general diagnostic tools and outline the criteria but do not operationalize them. The second set, the State of California Alzheimer's Disease Diagnostic and Treatment Centers[3] and the National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherche at L'Enseignement en Neurosciences (NINDS–AIREN)[4] criteria, are developments of the first two and offer operational criteria.

There are three fundamental flaws and several lesser errors lying in the details of these criteria. All the criteria are fundamentally similar in that they first require the presence of dementia, which is based on Alzheimer's disease (AD)-type features, and subsequently identify vascular dementia as a subset of all dementia, using vascular features that are often operationalized using the ischaemic score[5].

Unfortunately, the use of Alzheimer-based criteria for the diagnosis of dementia has now been clearly shown to be wrong. Vascular dementia does not closely resemble AD, even when Alzheimer-based criteria have been used for case identification[6]. Thus, cases selected using current criteria represent only a subset of all vascular dementia. This is the first major flaw in the current criteria.

The second problem is the increasing recognition of mixed dementia. Originally, vascular dementia and AD were separated by the presence of large infarct volumes[7]. In the nun study, in which 47% of demented patients had mixed disease, very small amounts of cerebrovascular disease profoundly altered the age of presentation and speed of progression of what otherwise appeared to be AD[8]. Reclassification of autopsy data to allow small infarct volumes to convert a diagnosis of AD to mixed dementia increased the proportion of cases with mixed dementia from 2% to 18%[9]. Thus, mixed dementia is far more important than was realized when the current criteria, which scarcely recognize mixed disease, were prepared. No good method yet exists for separating mixed dementia. Criteria that first select cases that appear like AD and then subselect those with vascular features might form an excellent basis for doing so; unfortunately, this is what the current criteria for vascular dementia do and it is very likely that much of the reported data about vascular dementia is in fact about mixed disease.

The next fault is the level of severity. The criteria define dementia as the level of cognitive impairment at which normal daily functions are impaired, and therefore will identify only late cases, underestimating the prevalence of cognitive impairment due to vascular disease. More importantly, they prevent identification of early cases that would benefit most from preventative treatment[14]. This important early stage has been termed "vascular cognitive impairment" (VCI)[10]. VCI is important because vascular disease is the largest single identifiable risk factor for dementia apart from age, and the only one currently treatable.

The above features constitute the fundamental faults of the current criteria. There are a number of additional problems that lie in their details. Differences in the details lead to great differences in the proportion of cases identified as having vascular dementia[3].

Correction of these faults requires wholesale revision of the criteria with the development of new criteria based on data rather than supposition[11–13].

Vascular Dementia

Peter Humphrey

Walton Centre for Neurology and Neurosurgery, Liverpool UK

EPIDEMIOLOGY

For many years, dementia was thought to be due to vascular disease. This seemed logical, largely on the basis that atherosclerosis and dementia are common in the elderly. In the 1970s and 1980s, many papers appeared stressing that vascular dementia was over-diagnosed[1], and most came to the conclusion that Alzheimer's disease (AD) was the commonest cause of dementia, even in patients who had had a stroke. In recent years the pendulum has swung a little back towards vascular disease being a more significant cause. Furthermore, the clear margins between some types of vascular dementia and AD have become blurred. Indeed, brain infarction may play an important part in determining the expression of the clinical symptoms of AD[2].

The epidemiology of vascular dementia is fraught with difficulties because of the lack of a reliable definition to act as a gold standard. Many groups have come to a different consensus about the criteria for the diagnosis (e.g. DSM-IV, ADDTC, NINDS–AIREN, ICD-10 and Hachinski score) Not only is the clinical diagnosis ambiguous, partly because many patients have mixed dementia (i.e. both AD and vascular disease), but the pathological differentiation of the varying types of dementia is also blurred. Does one then use clinical series, preferably community-based, or autopsy series? Reliable data are very sparse. Referral bias remains a major problem in hospital based series. In a community-based study in those aged over 85 from the USA, dementia was found in 30%[3]. In Europe and the USA, vascular disease accounts for 10–40% of all cases of dementia, whereas in Japan vascular disease is more common than AD; the lifetime risk of developing vascular dementia is approximately 25%[4–6]. Pathological studies suggest that cases of mixed AD and vascular dementia may be as common as those with just vascular dementia.

Equally good reasons can be made for thinking that vascular dementia remains both underdiagnosed and overdiagnosed[7,8]. Dementia is common following stroke occurring in approximately 16% after the first stroke[9].

RISK FACTORS

The risk factors for vascular dementia have rarely been studied in isolation to stroke. The major risk factors are age, race, hypertension, diabetes mellitus, hyperlipidaemia, smoking, transient ischaemic attack and heart disease, especially ischaemic heart disease and atrial fibrillation[10]. The level of education, volume of cerebral loss, degree of cerebral atrophy and presence of periventricular white matter lesions are important in the development of dementia[11]. Other possible risk factors include polycythaemia, homocysteinuria, hyperfibrinogenaemia, alcohol excess and lack of physical exercise.

Most of these risk factors predispose to the atherosclerotic process in all its many guises (e.g. large vessel atherosclerosis, small vessel lacunae and white matter leukoaraiosis). However, there are a number of other causes for vascular dementia which are worthy of separate mention. In the last 10 years our understanding that genetic factors can predispose to vascular disease have gained increasing importance, with the detailed understanding of the families with cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), mitochondrial diseases and hereditary cerebral haemorrhage with amyloid[12–14]. CADASIL has been shown to be linked to chromosome 19: individuals are predisposed to migraine, vascular events and dementia[12]. The genetics of mitochondrial encephalomyopathy with lactic acid and stroke-like episodes (MELAS) is of interest; only men are affected, with the disease being transmitted only by the maternal line. The clinical features include stroke-like episodes, lactic acidosis, short stature and deafness[13]. The diagnosis is confirmed by DNA analysis to look for point mutations in the RNA gene. Other rare causes of multi-infarct dementia and stroke include the anti-phospholipid syndrome[15,16], arteritis[17] and late effects of cranial radiotherapy, amongst others[18–20].

CLINICAL TYPES

The pathological findings in vascular dementia are diverse. Findings range from large cortical infarctions (Figure 48.1) to small discrete deep infarcts (Figure 48.2) and to diffuse areas of white matter low-attenuation changes as seen on CT scan (Figure 48.3). Several of these changes may co-exist in the same patient (Figure 48.4).

Cortical Infarcts

Multiple cortical thrombo-embolic infarcts are a common cause of multi-infarct dementia. This will follow embolic occlusions from either the heart or the great vessels, primarily in the neck, e.g. carotid stenosis, or primary thrombosis in the major cortical arteries of the cerebral hemispheres, e.g. antiphospholipid syndrome[15,16] and arteritis[17]. Dementia may rarely result from multiple watershed infarcts in the territories between the middle and posterior cerebral arteries in the cortex: hypotension is the usual cause secondary to prolonged cardiac arrest.

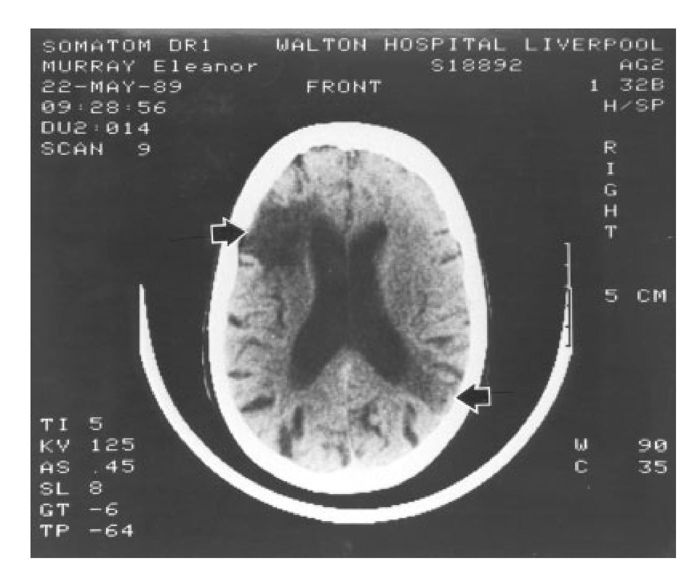

Figure 48.1 Multiple cortical infarcts

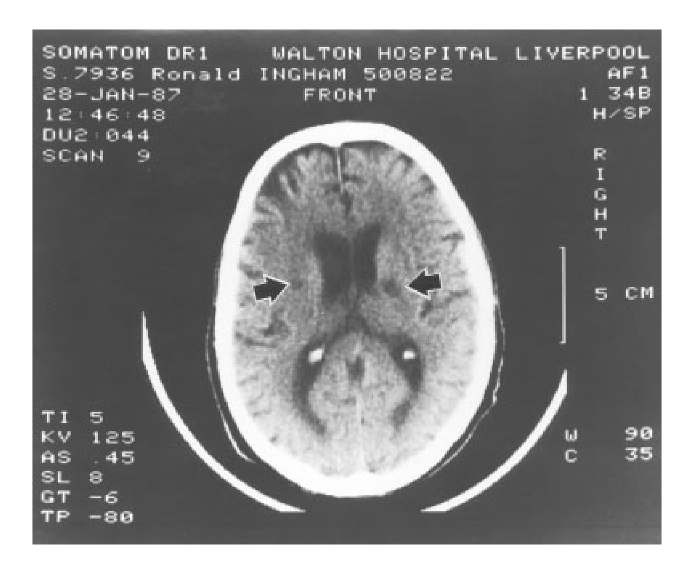

Figure 48.2 Multiple lacunae

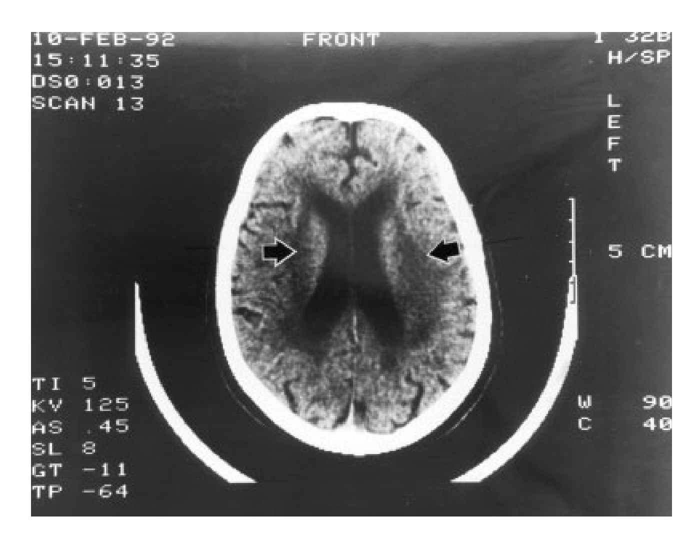

Figure 48.3 Leukoaraiosis

Figure 48.4 Cortical infarcts, lacunae and leukoaraiosis coexisting in the same patient

A strategic single cortical infarct in the dominant angular gyrus can also cause a picture similar to AD with dysphasia, visuospatial disorientation, agoraphobia and memory loss. Multiple cerebral haemorrhage, which particularly occurs in cerebral amyloid, may cause dementia.

Lacunar Infarction

Lacunae are small deep sub-cortical infarcts or haemorrhages. A single lacunar stroke commonly presents with pure motor hemiplegia, pure hemisensory loss or ataxic hemiparesis[21]. Multiple lacunae (état lacunaire) was described by Marie to produce dementia, dysarthria, small-stepping gait, incontinence and emotional lability. Fisher doubted the existence of a multi-lacunar dementia, although there is now no doubt that vascular dementia does occur after multiple lacunar infarcts[22,23]. Lacunar infarcts are common in hypertension and rarely follow embolic occlusion from the heart or major arteries.

While multi-infarct dementia is nearly always secondary to multiple lesions, it is possible to see memory loss after a single infarct. Discrete thalamic infarction especially in the paramedian region, may present as memory loss, often associated with somnolence and eye movement disorders[24,25].

Leukoaraiosis

This is largely a radiological diagnosis describing the diffuse or patchy low-attenuation changes seen on CT or MRI scans in the deep white matter[26]. Binswanger (1894) described eight patients with slowly progressive dementia who, at post mortem, were found to have softening and loss of deep white matter with compensatory ventricular enlargement. There is also gliosis, thickening of the arteries, within the abnormal white matter; many also show discrete lacunar infarction, although these are often too small to be seen on CT and MRI scanning. The

diagnosis of Binswanger's disease (subcortical arteriosclerotic encephalopathy; SAE) has become increasingly popular.

It was initially thought that these CT findings were specific for Binswanger's disease. However, similar CT findings can occasionally be seen in normal people or even those with AD. Because of this, the term "leukoaraiosis" (Greek, for white matter of loose texture) was used to describe the CT appearances[27].

Clinically there is a stepwise or progressive course, characterized by pseudo-bulbar palsy, cognitive, behavioural and gait disturbances, with focal neurological deficits in approximately 30%. The dementia tends to be subcortical in type. Many patients are hypertensive and the pathological changes are thought to be secondary to chronic ischaemia in the deep end arteries.

Although many patients are hypertensive, the final insult is probably due to hypoperfusion. Indeed, Sulkara and Erkinjunti have reported acute dementia after periods of hypotension and cardiac arrhythmia; CT showed leukoaraiosis[28]. Although hypertension needs to be treated, episodes of hypotension need to be carefully avoided, as vasodilatory reserve is impaired[29].

Inzitari *et al*. noted leukoaraiosis to be present in 100% of patients with multi-infarct dementia (MID) and 33% with AD compared with 11% of the control population, although even in this control population there was evidence of intellectual fall-off, but not severe enough to be labelled dementia[30]. A history of stroke was four times more likely in those with leukoaraiosis than in those without; most, however, die from cardiac causes[31]. Overall there appears to be considerable overlap between leukoaraiosis, subcortical atherosclerotic encephalopathy and multiple lacunar states.

In CADASIL, the MRI usually shows a combination of leukoaraiosis and multiple lacunar infarction.

Cerebral Amyloid Angiopathy

Although cerebral amyloid angiopathy has been known about for many years, its role in the aetiology of dementia has attracted much attention[32]. Amyloid deposition in the small and medium-sized arteries and arterioles may present with spontaneous haemorrhage or thrombosis. More interestingly, there have now been many reports of cerebral amyloid angiopathy (CAA) presenting as dementia without any preceding history of stroke-like episodes. CAA is associated with areas of small subcortical infarction and histological changes similar to Binswanger's SAE.

Senile plaques in AD contain an amyloid core which appears to be identical to CAA. Amyloid plaque cores are often found immediately adjacent to amyloid-laden capillaries. CAA is present in more than 80% of cases of AD[33].

The association of AD with leukoaraiosis and cerebral amyloid angiopathy has renewed speculation that vascular risk factors may play a role in the pathogenesis of AD[34].

MANAGEMENT

Clinical Assessment

The following criteria point towards a diagnosis of vascular dementia:

1. Symptoms and signs of stepwise stroke-like episodes.
2. Vascular risk factors.
3. Evidence of vascular disease on CT and MRI.

The validity of the different scoring systems is discussed elsewhere (q.v.). Factors suggesting that the dementia is not vascular include:

1. Absence of the above.
2. Early presence of extrapyramidal and autonomic features.
3. Early hallucinations.
4. Cerebellar signs.

It should be noted that it is sometimes difficult in those who present with gait problems to distinguish leukoaraiosis/multiple lacunar strokes from normal pressure hydrocephalus and progressive supranuclear palsy: it is important, then, to look for poor upgaze, axial rigidity and perform CT or MRI scanning.

There is no single illness making up vascular dementia. The clinical management of any patient with vascular dementia should include a summary of the clinical presentation, the probable pathogenesis, risk factors and site of damage. This will allow a rational approach to investigation and medical treatment to minimize the risk of further recurrence/progression. An attempt should be made to decide whether the dementia is primarily a thrombotic or an embolic process from the heart or great vessels, a hypertensive deep white matter disease, a hypoperfusion process or even one of the rarer causes of stroke.

Investigation

Investigation should include a routine vascular screen and then further investigations, depending on the proposed pathophysiology. It is important to assess the routine vascular risk factors, especially as Meyer *et al*. have suggested that improved cognition may occur after the control of risk factors in MID[35]. A careful assessment of the cardiovascular system is necessary, particularly paying attention to blood pressure and possible sites of emboli from the cerebral arteries (i.e. carotid stenosis) and heart, (especially valvular heart disease, atrial fibrillation or tumour and left ventricular thrombus) in those with cortical infarctions. The CT/MRI scan appearances in vascular dementia have already been discussed in some detail.

All patients should have a full blood count (for polycythaemia or thrombocythaemia), ESR (for arteritis), blood sugar, chest X-ray and ECG. I also check fasting lipids, as cholesterol is an important risk factor for ischaemic heart disease and most vascular patients die a cardiac death. Neurosyphilis remains treatable. Evidence of arteritis and the antiphospholipid syndrome should be looked for, both clinically and by checking various blood tests, such as CRP, complement levels, antinuclear factor, DNA binding, lupus anticoagulant and anticardiolipin antibodies. If the ESR is raised or the patient is over 50 it is important to consider the arteritides, such as granulomatous angiitis and temporal arteritis[17,36].

The diagnosis of granulomatous angiitis can be very difficult and may require both angiography and brain/meningeal biopsy. It is often difficult to know how often one should pursue these investigations, but a stuttering onset of recent vascular dementia with a raised ESR and abnormal lymphocytic cerebrospinal fluid (CSF) should alert the physician. Unfortunately, in some cases the ESR and CSF may be normal. A high index of suspicion is needed because with steroids and cyclophosphamide these patients can do very well[17,20]. In spite of this, a raised ESR in stroke frequently remains unexplained.

Ultrasound scanning of the carotid arteries to detect carotid stenosis or occlusion may be appropriate, although these usually cause transitory ischaemic attacks or strokes, rather than a dementia[37].

Echocardiography is important if a cardiac source of emboli is considered possible and should be performed in all patients with more than one cortical infarct[18].

Skin biopsy, chromosome and DNA analysis may be helpful in the diagnosis of CADASIL and MELAS. Measuring cerebral

blood flow and metabolism has become increasingly more sophisticated with the advent of positron emission tomography (PET) which uses radioactive tracers to measure metabolism and blood flow. Frackowiak *et al*. showed that cerebral blood flow (CBF) and metabolism fell with increasing dementia in both MID and degenerative dementia[38]. Normal CBF is 50–70 ml/100 g/min: ischaemia only occurs once the CBF falls below 10–20 ml/100 g/min. Focal abnormalities are found in both MID and degenerative dementia, although in the vascular group the individual focally deranged areas are patchy and match the unique patterns of ischaemic damage, whereas in AD the focal abnormalities are mainly temporoparietal. PET largely remains a research tool.

Single photon emission CT (SPECT) is becoming a more widely available tool, as most X-ray departments have the necessary equipment. Radioactive tracers are used to measure blood flow. Similar temporoparietal abnormalities in AD and patchy irregularities in MD have been reported[39]. However, all these studies have used a clinical scoring system with/without CT to differentiate MID and AD. None have had pathological confirmation. Because only 10–20% of dementias are multi-infarct, and because an approximate equal percentage have mixed disease (stroke with coincidental AD), it will not be possible to know the true value of PET and SPECT until serial studies are performed with pathological confirmation.

Treatment

As with all vascular disease treatment initially involves dealing with the risk factors—hypertension, hyperlipidaemia, diabetes mellitus and smoking. The Syst-Eur Hypertension trial has demonstrated that treating hypertension prevents dementia[40]. This is combined with specific treatment for the underlying disease process. Aspirin is of proven value in preventing stroke[41]. Whether adding dipyridamole to aspirin confers any greater benefit than aspirin alone remains debatable[42,43]. There is no doubt that clopidogrel is a new effective antiplatelet agent at least as good as aspirin; it should be considered in those intolerant of aspirin[44].

Warfarin is the treatment of choice in those with atrial fibrillation, but the risk of haemorrhage secondary to warfarin is higher in those with leukoaraiosis[45,46]. It must be used with caution if poor compliance and falls are a problem. Anticoagulation should also be considered in the antiphospholipid syndrome[16].

In spite of the many claims, no vasodilator, calcium antagonist or neuroprotective agent has been shown to help vascular dementia. Steroids and immunosuppression may be indicated if an arteritis is proven.

Tatemichi[37] has published a case of dementia with bilateral internal carotid occlusions which improved after extracranial–intracranial bypass surgery to improve the blood flow to the brain.

This section has dealt with the specific treatments for vascular disease: it is crucial, of course, to provide symptomatic treatment and a full care package for the many other problems the unfortunate patient with vascular dementia may experience.

Vascular Dementia Subgroups: Multi-infarct Dementia and Subcortical White Matter Dementia

Ingmar Skoog

Sahlgrenska University Hospital, Göteborg, Sweden

Until the 1960s, almost all dementias of old age were considered secondary to "hardening of the arteries" and chronic ischaemia. In the next decades, vascular causes of dementia came to be considered rare, and multi-infarct dementia (MID) almost its only cause. The term "vascular dementia" (VaD) was introduced in the 1990s to emphasize that several cerebrovascular disorders might cause dementia.

An ischaemic stroke increases the risk for dementia several-fold[1]. The dementias related to stroke are MID and strategic infarct dementia. MID is related to multiple small or large brain infarcts, often too small individually to produce a major clinical incident. The typical patient has a history of stroke or transitory ischaemic attacks with acute focal neurological symptoms and signs. The clinical picture includes sudden onset, stepwise deterioration and a fluctuating course of the dementia. In the early stages, the cognitive impairment may have a large variability, depending on the site of the lesions. However, in a large minority of cases the dementia may have a gradual onset, with a slowly progressive course[2] and without focal signs or infarcts on brain imaging (especially when computed tomography has been used), which makes it difficult to differentiate from AD. It has been suggested that the dementia may be related to the location or the volume of the infarcts. The risk factors suggested for MID are similar to those in stroke, including advanced age, male sex, hypertension, diabetes mellitus, smoking and cardiac diseases[3].

Ischaemic white matter lesions (WMLs) were first described in cases of dementia by Durand-Fardel in 1854, followed by Binswanger in 1894, and by Alzheimer in 1898. Fewer than 50 autopsied cases were described up to 1980[4]. In the 1980s, when WMLs became possible to discern on brain imaging, they were suddenly reported in thousands of patients. Before the advent of brain imaging, the level of interest in white matter disorders among pathologists was low and the white matter was not routinely evaluated in most patients. The pathologic description includes marked or diffuse demyelination and moderate loss of axons, with astrogliosis and incomplete infarction in subcortical structures of both hemispheres, and arteriosclerotic changes, with *hyalinization or fibrosis and thickening of the vessel walls and narrowing of the lumen of the small penetrating arteries and arterioles in the white matter*. The main hypothesis regarding the cause of WMLs is that long-standing hypertension causes *lipohyalinosis and thickening of the vessel walls, with narrowing of the lumen of the small perforating arteries and arterioles which nourish the deep white matter*[4]. The dementia is probably caused by subcortical–cortical or cortico–cortical disconnection, and is generally of a subcortical type with extrapyramidal signs, especially psychomotor retardation. A frontal lobe syndrome with apathy, loss of drive and emotional blunting is common.

Regarding the subtypes of VaD, there is a discussion between lumpers and splitters. In the NINDS–AIREN criteria[6], MID and WMLs are lumped together and it has been questioned whether present scientific knowledge permits anything more than a broad definition of VaD. Focal neurological deficits and brain infarcts are common in subjects with WMLs, and the presence of WMLs are reported to increase the risk for dementia in subjects with stroke. The reason for the common co-occurrence of stroke and WMLs may be that they share similar risk factors, mainly hypertension. However, not all demented subjects with WMLs have cortical infarcts in their brains, and not all individuals with MID have WMLs. Therefore, it may be better to adopt the splitting view to better categorize these entities, with the understanding that there is a large overlap.

There is also an overlap between VaD and AD. WMLs have been described in a high proportion of cases with AD on both brain imaging and at autopsy, and they seem to be more common in late-onset than in early-onset AD[4]. It has even been suggested that white matter degeneration precedes and causes the cortical atrophy in AD[5]. A considerable proportion of subjects from the general population fulfilling the research criteria for AD or VaD

Vascular Dementia Subgroups: Multi-infarct Dementia and Subcortical White Matter Dementia

Ingmar Skoog
Sahlgrenska University Hospital, Göteborg, Sweden

Until the 1960s, almost all dementias of old age were considered secondary to "hardening of the arteries" and chronic ischaemia. In the next decades, vascular causes of dementia came to be considered rare, and multi-infarct dementia (MID) almost its only cause. The term "vascular dementia" (VaD) was introduced in the 1990s to emphasize that several cerebrovascular disorders might cause dementia.

An ischaemic stroke increases the risk for dementia several-fold[1]. The dementias related to stroke are MID and strategic infarct dementia. MID is related to multiple small or large brain infarcts, often too small individually to produce a major clinical incident. The typical patient has a history of stroke or transitory ischaemic attacks with acute focal neurological symptoms and signs. The clinical picture includes sudden onset, stepwise deterioration and a fluctuating course of the dementia. In the early stages, the cognitive impairment may have a large variability, depending on the site of the lesions. However, in a large minority of cases the dementia may have a gradual onset, with a slowly progressive course[2] and without focal signs or infarcts on brain imaging (especially when computed tomography has been used), which makes it difficult to differentiate from AD. It has been suggested that the dementia may be related to the location or the volume of the infarcts. The risk factors suggested for MID are similar to those in stroke, including advanced age, male sex, hypertension, diabetes mellitus, smoking and cardiac diseases[3].

Ischaemic white matter lesions (WMLs) were first described in cases of dementia by Durand-Fardel in 1854, followed by Binswanger in 1894, and by Alzheimer in 1898. Fewer than 50 autopsied cases were described up to 1980[4]. In the 1980s, when WMLs became possible to discern on brain imaging, they were suddenly reported in thousands of patients. Before the advent of brain imaging, the level of interest in white matter disorders among pathologists was low and the white matter was not routinely evaluated in most patients. The pathologic description includes marked or diffuse demyelination and moderate loss of axons, with astrogliosis and incomplete infarction in subcortical structures of both hemispheres, and arteriosclerotic changes, with *hyalinization or fibrosis and thickening of the vessel walls and narrowing of the lumen of the small penetrating arteries and arterioles in the white matter*. The main hypothesis regarding the cause of WMLs is that long-standing hypertension causes *lipohyalinosis and thickening of the vessel walls, with narrowing of the lumen of the small perforating arteries and arterioles which nourish the deep white matter*[4]. The dementia is probably caused by subcortical–cortical or cortico–cortical disconnection, and is generally of a subcortical type with extrapyramidal signs, especially psychomotor retardation. A frontal lobe syndrome with apathy, loss of drive and emotional blunting is common.

Regarding the subtypes of VaD, there is a discussion between lumpers and splitters. In the NINDS–AIREN criteria[6], MID and WMLs are lumped together and it has been questioned whether present scientific knowledge permits anything more than a broad definition of VaD. Focal neurological deficits and brain infarcts are common in subjects with WMLs, and the presence of WMLs are reported to increase the risk for dementia in subjects with stroke. The reason for the common co-occurrence of stroke and WMLs may be that they share similar risk factors, mainly hypertension. However, not all demented subjects with WMLs have cortical infarcts in their brains, and not all individuals with MID have WMLs. Therefore, it may be better to adopt the splitting view to better categorize these entities, with the understanding that there is a large overlap.

There is also an overlap between VaD and AD. WMLs have been described in a high proportion of cases with AD on both brain imaging and at autopsy, and they seem to be more common in late-onset than in early-onset AD[4]. It has even been suggested that white matter degeneration precedes and causes the cortical atrophy in AD[5]. A considerable proportion of subjects from the general population fulfilling the research criteria for AD or VaD

have mixed pathologies[7,8]. Cerebrovascular diseases may increase the possibility that individuals with AD lesions in their brains will express a dementia syndrome[9], and "post-stroke dementia" is often a mixture of the direct consequences of stroke, pre-existing AD pathology and the additive effects of these lesions and ageing[10]. The coincidence of AD and VaD may even be the most common form of dementia.

The Role of Blood Pressure in Dementia

Ingmar Skoog

Sahlgrenska University Hospital, Göteborg, Sweden

The association between hypertension and dementia/cognitive impairment has received increased interest recently. Both the Honolulu–Asia Aging Study[1] and the Framingham Study[2] report that low performance in psychometric tests in the population is related to a higher systolic blood pressure decades before the measurement of cognitive function. We found that systolic and diastolic blood pressure was increased 10–15 years before the onset of both Alzheimer's disease (AD) and vascular dementia, as well as in individuals with white matter lesions[3]. Furthermore**,** middle-aged non-demented hypertensive individuals have an increased amount of senile plaques and neurofibrillary tangles, the histopathological hallmarks of AD, in their brains[4]. In cross-sectional studies, blood pressure is generally negatively correlated to cognitive performance before age 75, while there is a positive correlation above that age. Furthermore, elderly subjects with already manifested AD and vascular dementia have lower blood pressure than the non-demented[5]. Thus, although previously high blood pressure seems to be related to cognitive decline and dementia, low blood pressure is often related to already manifested dementia.

Several mechanisms may be involved in the association between hypertension and dementia/cognitive decline. First, the risk of stroke increases with inceasing blood pressure, and stroke is a strong risk factor for dementia. It is thus reasonable to believe that high blood pressure is a risk factor for stroke-related dementia. Hypertension is also a risk factor for ischaemic subcortical white-matter lesions (WMLs)[6], which are often found in subjects with late-onset AD and multi-infarct dementia (MID). The main hypothesis regarding the cause of WMLs is that longstanding hypertension causes lipohyalinosis and thickening of the vessel walls, with narrowing of the lumen of the small perforating arteries and arterioles that nourish the deep white matter. Episodes of hypotension may lead to hypoperfusion and hypoxia–ischaemia, leading to loss of myelin in the white matter. It has been suggested that the arterial changes are due to exposure of vessel walls to increased pressure over time. The greater the pressure and/or lifespan, the more likely are these changes to be present.

A third explanation is that chronic hypertension may lead to a dysfunction of the the blood–brain barrier (BBB), with increased permeability of the endothelial cell layer and extravasation of serum proteins[7]. The CSF:serum albumin ratio is a generally accepted method of assessing the BBB function in living subjects. We recently found that AD, MID and severe forms of WMLs were all associated with an increased CSF:serum albumin ratio in a population-based study of 85 year-olds[8]. A breakdown in the BBB may cause brain lesions by cerebral oedema, activation of astrocytes, or destructive enzymes or other poisons that pass through the damaged vessel walls. Fourth, the renin–angiotensin system is an example of a system that may be involved in the pathogenesis of both hypertension and dementia[9]. Its effector peptide, angiotensin II, has several blood pressure increasing effects, promotes hyperplasia and hypertrophy in vascular smooth muscle cells, and affects memory and behaviour. Fifth, psychological stress has been suggested to be a risk factor for both hypertension and dementia[10].

The association between low blood pressure and dementia has several explanations. First, systemic hypotension associated with reduced cerebral blood flow may give rise to a spectrum of ischaemic neuronal lesions in the brain and may also lead to ischaemic loss of myelin in the white matter. Second, several of the blood pressure-regulating areas in the central nervous system are affected in dementia disorders. Therefore, dementia disorders and their associated brain changes may *per se* influence the blood pressure[5]. A correlation between the number of C-1 neurons in the medulla oblongata and blood pressure has been reported in AD[11]. Blood pressure decline during the course of AD, and low blood pressure was related to cerebral atrophy in non-demented 85 year-olds[5]. It thus seems likely that low blood pressure in demented individuals is secondary to the brain lesions. If cerebral disorder

The Role of Blood Pressure in Dementia

Ingmar Skoog
Sahlgrenska University Hospital, Göteborg, Sweden

The association between hypertension and dementia/cognitive impairment has received increased interest recently. Both the Honolulu–Asia Aging Study[1] and the Framingham Study[2] report that low performance in psychometric tests in the population is related to a higher systolic blood pressure decades before the measurement of cognitive function. We found that systolic and diastolic blood pressure was increased 10–15 years before the onset of both Alzheimer's disease (AD) and vascular dementia, as well as in individuals with white matter lesions[3]. Furthermore, middle-aged non-demented hypertensive individuals have an increased amount of senile plaques and neurofibrillary tangles, the histopathological hallmarks of AD, in their brains[4]. In cross-sectional studies, blood pressure is generally negatively correlated to cognitive performance before age 75, while there is a positive correlation above that age. Furthermore, elderly subjects with already manifested AD and vascular dementia have lower blood pressure than the non-demented[5]. Thus, although previously high blood pressure seems to be related to cognitive decline and dementia, low blood pressure is often related to already manifested dementia.

Several mechanisms may be involved in the association between hypertension and dementia/cognitive decline. First, the risk of stroke increases with inceasing blood pressure, and stroke is a strong risk factor for dementia. It is thus reasonable to believe that high blood pressure is a risk factor for stroke-related dementia. Hypertension is also a risk factor for ischaemic subcortical white-matter lesions (WMLs)[6], which are often found in subjects with late-onset AD and multi-infarct dementia (MID). The main hypothesis regarding the cause of WMLs is that longstanding hypertension causes lipohyalinosis and thickening of the vessel walls, with narrowing of the lumen of the small perforating arteries and arterioles that nourish the deep white matter. Episodes of hypotension may lead to hypoperfusion and hypoxia–ischaemia, leading to loss of myelin in the white matter. It has been suggested that the arterial changes are due to exposure of vessel walls to increased pressure over time. The greater the pressure and/or lifespan, the more likely are these changes to be present.

A third explanation is that chronic hypertension may lead to a dysfunction of the the blood–brain barrier (BBB), with increased permeability of the endothelial cell layer and extravasation of serum proteins[7]. The CSF:serum albumin ratio is a generally accepted method of assessing the BBB function in living subjects. We recently found that AD, MID and severe forms of WMLs were all associated with an increased CSF:serum albumin ratio in a population-based study of 85 year-olds[8]. A breakdown in the BBB may cause brain lesions by cerebral oedema, activation of astrocytes, or destructive enzymes or other poisons that pass through the damaged vessel walls. Fourth, the renin–angiotensin system is an example of a system that may be involved in the pathogenesis of both hypertension and dementia[9]. Its effector peptide, angiotensin II, has several blood pressure increasing effects, promotes hyperplasia and hypertrophy in vascular smooth muscle cells, and affects memory and behaviour. Fifth, psychological stress has been suggested to be a risk factor for both hypertension and dementia[10].

The association between low blood pressure and dementia has several explanations. First, systemic hypotension associated with reduced cerebral blood flow may give rise to a spectrum of ischaemic neuronal lesions in the brain and may also lead to ischaemic loss of myelin in the white matter. Second, several of the blood pressure-regulating areas in the central nervous system are affected in dementia disorders. Therefore, dementia disorders and their associated brain changes may *per se* influence the blood pressure[5]. A correlation between the number of C-1 neurons in the medulla oblongata and blood pressure has been reported in AD[11]. Blood pressure decline during the course of AD, and low blood pressure was related to cerebral atrophy in non-demented 85 year-olds[5]. It thus seems likely that low blood pressure in demented individuals is secondary to the brain lesions. If cerebral disorder

causes low blood pressure, the question arises whether cerebral changes may induce high blood pressure. Recently, it was shown that infusion of $A\beta_{42}$ (a protein deposited in the brains and cerebral vessels of AD victims) increased blood pressure in anaesthetized rats, suggesting that circulating levels of this protein may exert vasopressor actions *in vivo*[12].

Treatment of hypertension may thus have a preventive effect on cognitive decline and dementia. The recent finding from the Syst-Eur trial[13], that treatment of isolated systolic hypertension reduces the incidence of dementia by 50%, supports this hypothesis, but the number of demented in that study was small. It has been suggested that overtreatment with antihypertensive drugs may increase the risk of dementia in the very old by causing cerebral hypoperfusion. No studies so far provide support for this opinion. We recently reported[14] that subjects who became demented during a 15-year follow-up used antihypertensive drugs less often than those who did not become demented. Although these findings do not preclude the possibility that overtreatment of hypertension may cause ischaemia in the brain in a subset of individuals, they do not support the hypothesis that antihypertensive treatment may cause cognitive impairment in the elderly.

Neuropathology: Other Dementias

J. M. MacKenzie

Grampian University Hospitals NHS Trust, Aberdeen, UK

There are many causes of dementia in addition to Alzheimer's disease (AD) and vascular dementia, and the commonest of these seems to be dementia with Lewy bodies (DLB), which perhaps accounts for 10% of all cases of dementia, although the precise incidence depends on the population studied and the pathological criteria used for diagnosis[1,2]. In a hospital series, it may be second only to AD as a cause of dementia[3]. After DLB, other causes are distinctly rare and include Creutzfeldt–Jakob disease, Huntington's disease and the frontotemporal dementias.

DEMENTIA IN PARKINSON'S DISEASE AND DEMENTIA WITH LEWY BODIES

Parkinson's disease is a disorder characterized by rigidity, tremor and bradykinesia, usually with an onset in the sixth decade. Neuronal loss and gliosis are typically evident in the substantia nigra and loci coerulei, but also in the dorsal vagal nuclei, dorsal raphe nuclei and nucleus basalis of Meynert. Lewy bodies, spherical intracytoplasmic inclusions composed of granular and filamentous elements, immunoreactive with antibodies against neurofilament protein, paired helical filaments, ubiquitin and, in aminergic neurones, tyrosine hydroxylase protein[4–7], are found not only in pigmented brainstem neurones but also in over 20 different nuclei, pigmented and non-pigmented[8]. Changes in aminergic pathways, particularly dopaminergic, are well documented[4].

Dementia has been reported to affect 34.6% of patients with parkinsonism in one large autopsy series and it seems likely that a number of different mechanisms are responsible[9].

Concurrent AD

It has been claimed that AD is six times more common in patients with Parkinson's disease than in age-matched controls[10] and 12–25% of demented parkinsonian patients in one series had AD[4].

In Jellinger's study[9], most of the demented parkinsonians also had the pathological changes of AD. Other studies have shown that cortical senile plaques and neurofibrillary tangles are more numerous in demented patients with Parkinson's disease than non-demented Parkinson's disease sufferers or controls[11–13]. The wide spectrum of dementia in Parkinson's disease has been attributed to the overlap of clinical and subclinical pathological changes in both diseases[14].

Innominato-cortical Dysfunction

Neuronal loss from the basal nucleus of Meynert (BNM) is greater in demented than in non-demented parkinsonian patients[11] and this depletion may be 40–80% in the former as opposed to 20–50% in the latter[15,16].

Furthermore, there is also evidence of an accompanying reduction in choline acetyltransferase (CAT) and acetylcholinesterase in the BNM and all areas of the cerebral cortex. Decreased CAT activity in the temporal cortex correlates with BNM neuronal loss in Parkinson's disease, unlike AD, and also correlates with memory impairment, although not with the numbers of cortical plaques and tangles[17].

Neuronal Loss in Pigmented Brainstem Nuclei

It is generally stated that there is no correlation between neuronal loss in the substantia nigra and mental impairment[11], but it has been found that neuronal loss in the medial substantia nigra correlates with the severity of dementia, presumably due to loss of projections to the caudate nuclei, limbic system and cerebral cortex[18]. In addition, severe neuronal loss and subnormal noradrenaline metabolism in the loci coerulei are commoner in demented than non-demented parkinsonian patients[11,19]. Medial substantia nigra loss, together with cortical AD changes, seemed to underlie dementia in one study, whereas depression in Parkinson's disease was associated with more severe loss of neurones from the dorsal raphe nuclei[13].

Dementia with Lewy Bodies

Small numbers of Lewy bodies may be present in the cerebral cortex in patients without neurological impairment, or with Parkinson's disease. However, a disorder characterized by early neuropsychiatric features, dementia, visual hallucinations, fluctuating conscious level and relatively mild Parkinson's disease justifies separate identification as DLB[20] because of different therapeutic implications. Many cases also have large numbers of brainstem Lewy bodies and it seems likely that DLB, with a predominantly cortical distribution of Lewy bodies, lies at one end of a spectrum of Lewy body disorders, in which idiopathic Parkinson's disease, with Lewy bodies predominantly localized in the brainstem, is the opposite end[21].

In many reported cases, cortical Lewy bodies have been associated with AD-type changes, leading to the conclusion that

the cause of dementia in diffuse LBD is cortical[22,23]. However, the distribution of neuritic plaques and neurofibrillary tangles does not necessarily parallel the distribution of Lewy bodies[24] and, in some cases with Lewy bodies in the cerebral cortex and brainstem nuclei, AD-type changes are not present[25].

The precise nosological relationship between DLB and AD, and between DLB and patients with Parkinson's disease who subsequently become demented, requires elucidation[3].

CREUTZFELDT–JAKOB DISEASE

Creutzfeldt–Jakob disease (CJD) belongs to the family of transmissible spongiform encephalopathies affecting humans and animals[26]. In humans the main forms are sporadic CJD, iatrogenic CJD (associated mostly with pituitary hormones prepared from cadaver pituitaries), familial forms, including Gerstmann–Straussler–Scheinker (GSS) syndrome and variant CJD (vCJD).

Sporadic CJD is typically a rapidly progressive dementia with associated myoclonus, but a number of different clinical and pathological variants have been described[27,28]. The worldwide incidence is approximately 1–2/million/year[29], although the average annual incidence in England and Wales was 0.3 in 1970–1979[30], and 0.49 in 1980–1984[31]. The highest reported incidence of 75 is amongst Libyan Jews[32]. Although often a presenile dementia, the peak age-specific mortality rate in England and Wales is in the seventh decade, with a mean of 63.2 years and a range of 33–82[31].

Approximately 10–15% of cases of CJD are familial and seem to follow an autosomal dominant pattern of inheritance[33]. GSS is also familial, but clinically and pathologically more closely resembles kuru than CJD, although caused by the same transmissible agent[34,35].

To date, there has been only one reported case of vCJD in the elderly[36a]. All of the other cases have been younger (mean age at death 29 years). The presenting features in both age groups are behavioural change and sensory symptoms with later development of cerebellar ataxia, dementia and mycoclonus[36].

Although pathological variants of CJD have been described, the principal features are fluctuating spongiform change of the grey matter, with neuronal loss, and astrocytic hypertrophy and hyperplasia[37]. Amyloid plaques, particularly in the cerebellum, are present in 5–10% of cases of CJD and the majority of cases of kuru and GSS[34]. Florid amyloid plaques of prion protein are also characteristic of vCJD.

The transmissible nature of CJD has been known for many years[37,38]. Prions[39,40] as proteinaceous infectious particles consisting of one protein (PrP 27-30), which is encoded by a cellular gene and derived from a larger protein. PrP 27-30 is inseparable from the infectivity of the scrapie agent and constitutes the amyloid of cerebral plaques in "prion" diseases. The PrP or a closely-related gene clearly controls the clinical expression of the disease.

The causal relationship of PrP with the disease is strengthened by the presence of disease-specific mutations linked to, or tracking with, inherited "prion" diseases, such as the substitution of leucine for proline at PrP codon 102 in ataxic forms of GSS[41] and the substitution of lysine for glutamate at codon 200 in Libyan Jews[42]. Similarly, the valine 129 homozygous genotype is associated with susceptibility to iatrogenic CJD[43] and methionine 129 homozygosity with vCJD[36].

The continued unravelling of the molecular biology of the prion diseases is likely to reveal as many surprises in the future as have already been provided by this fascinating group of disorders. However, it seems improbable that "prion dementias" constitute a large group of as yet unrecognized neurodegenerative disorders and, for all practical purposes, transmissible spongiform encephalopathies in humans and "prion dementias", are the same[44].

HUNTINGTON'S DISEASE

Huntington's disease (HD) is a disorder of midlife onset (mean age 41 years) characterized by progressive chorea, psychological changes and dementia, although not necessarily in that order. The disease is encountered in the senium, sometimes because of prolonged survival of presenile cases, but also because chorea only appears in 28% of HD patients after the age of 50 and, occasionally, not until the seventh or eighth decade[45]. HD is inherited as an autosomal dominant trait with 100% penetrance and the HD gene has been localized near the telomere on the short arm of chromosome 4[46].

The principal neuropathological features are neuronal loss and gliosis in the corpus striatum, and a five-grade system has been devised for pathologically classifying HD[47], which closely correlates with the degree of clinical disability[48]. Most of the neuropathologically studied cases fall into Grades 2 and 3 (79%)[49]; 50% of neurones have been lost from the caudate nucleus by the time grade 1 pathological changes are recognizable and 95% by grade 4. There is an accompanying increase in astrocytes and oligodendrocytes, reaching a maximum that is significantly different from control material in grade 4 for the former and grades 0–2 for the latter[47].

The distribution of neuronal loss within the corpus striatum is non-uniform. In Grades 1 and 2 the medial caudate nucleus is more severely affected than the lateral, although this distinction is lost when the pathological changes become more severe[47]. The anteroventral part of the putamen is also spared[50]. Not only is the disease process in the corpus striatum anatomically variable, but also not all neuronal populations are equally affected. The small to medium-sized spiny neurones (which have a large synaptic surface and distant connections) are most affected in HD, and these neurones contain γ-aminobutyric acid (GABA) enkephalins and substance P[51,52]. On the other hand, medium aspiny neurones, containing NADPH-diaphorase, somatostatin and neuropeptide Y, and large cholinergic neurones, are relatively spared[53,54]. The decreased concentration of GABA and enzymes involved in its metabolism, which has been known for many years[55], together with the decreased concentrations of substance P and the enkephalins, can be explained on the basis of selective loss of striatal neuronal populations.

The disease is caused by expansion of a trinucleotide CAG repeat beyond 35 repeats in the first exon of the huntingtin gene on chromosome 4[56]. The CAG repeats are translated to polyglutamine repeats in huntingtin and, although the normal function of huntingtin is incompletely understood, it appears to be associated with the cytoskeleton and necessary for neurogenesis, and expression of mutant huntingtin is necessary for disease development. The ability of huntingtin to interact with other proteins is influenced by CAG length and it is possible that neuronal apoptosis may be triggered by abnormal interaction with caspase 3[57,58]. Furthermore, there is also evidence of abnormal metabolism in HD brain tissue, resulting in the generation of free radicals, so that more than one mechanism may be operating to produce cell death in HD[59].

Although corpus striatum changes dominate the pathological picture in HD, other areas of the brain are involved. The

cerebral cortex showed 21–29% loss of substance, the cerebral white matter 29–34% and the thalamus 28% in one study[60], but cortical abnormalities may be very difficult to identify[49]. Neuronal loss has been identified in the superior frontal and cingulate cortices, particularly of laminae III and V pyramidal neurones, but this does not seem to correlate with severity of striatal pathology, suggesting that it is a primary part of the disease process[61].

However, another study[62] found evidence of loss of large pyramidal neurones from laminae III, V and VI of the prefrontal cortex, which was most severe in pathological grade 4 HD, and suggested that this represented retrograde degeneration of cortical glutamatergic neurones. Nerve cell loss from specific regions of the entorhinal cortex and subiculum has also been reported[63].

There is controversy over whether neuronal loss in the substantia nigra does[64] or does not[65] occur in HD. Preservation of neuronal populations in the nucleus basalis of Meynert, locus coeruleus and dorsal raphe nuclei has also been reported, leading to the suggestion that dementia in HD may be due not to damage to subcortical nuclei, as in the other "subcortical" dementias, but to failure of ascending systems within the basal ganglia or neuronal loss in the cerebral cortex[65].

FRONTOTEMPORAL DEMENTIA

The frontotemporal dementias (FTD) are non-Alzheimer forms of dementia characterized clinically by behavioural and personality change leading to apathy and mutism, and by progressive atrophy of the frontal, anterior parietal and anterior temporal lobes. The histology is variable and defines three separate subgroups[66]:

- *Frontal lobe degeneration*. This is characterized by microvacuolar degeneration, gliosis and neuronal loss, principally affecting laminae II and III.
- *Pick's disease* (FTD with Pick-type histology) is represented by transcortical neuronal loss, gliosis and cavitation, together with the presence of tau and ubiquitin-positive intraneuronal inclusions (Pick bodies) and αB crystallin-positive ballooned neurones (Pick cells). Although there is overlap between Pick's disease and other forms of FTD, as well as with corticobasal degeneration, the distinctive distribution of the pathological changes—such as the involvement of the dentate fascia by Pick bodies—has led some authors to regard Pick's disease as a unique disease rather than a histological variant within the FTD spectrum[67]. However, both of these different histologies can have a variable topographical distribution in the brain, producing progressive language disorder when both temporal lobes are involved or the disease primarily affects the left hemisphere, or progressive apraxia when parietal and motor areas are involved[66].
- *Motor neurone disease inclusion dementia*. Either of these histologies can overlap with classical motor neurone disease, either as a dementing disorder occurring in patients known to have MND, or also as an identical histology occurring in patients without motor dysfunction[66,68].

Fifty-eight percent of cases of FTD show a previous family history of a similar disorder, and linkage to chromosome 17 has been established in some families. Following the current trend for "molecular" classification of the dementias, the various forms of FTD have sometimes been described as "tauopathies" but 64% cases of FTD in one study showed no intracellular tau-positive inclusions[69]. This is an area where further study and clarification is required.

OTHER DISORDERS

Many other disorders may be associated with dementia in the elderly, including progressive supranuclear palsy[70] and, occasionally, multiple sclerosis[71]. There are also a number of rare dementing disorders of uncertain nosological status, such as the tangle-predominant form of dementia[72] and argyrophilic grain disease[73].

This section of the book would not be complete without the reader being reminded of the estimated 13.2%[72] of causes of dementia in the elderly—including intracranial space-occupying lesions, particularly chronic subdural haematoma; metabolic disorders, such as hypothyroidism and hypopituitarism[75]; and "normal-pressure" hydrocephalus—that are potentially treatable[76].

Dementia and Parkinson's Disease

Richard B. Godwin-Austen

Queen's Medical Centre, Nottingham, UK

Although James Parkinson, in his 1817 monograph, believed that this disease left "the senses and intellects . . . uninjured", there has been increasing realization that Parkinson's disease (PD) is associated in many cases with dementia. The dementia has specific clinical and psychological characteristics and is now believed to be associated in the majority with specific neuropathological changes. Certainly, dementia in elderly patients with PD complicates their management, limits treatment and survival and leads to a heavy burden on medical and welfare services and family alike. The dementia of PD is therefore a subject of great importance, in which substantial advances in understanding have taken place in recent years.

In cases where parkinsonism and dementia coexist, the differential diagnosis must include Lewy body dementia (LBD), progressive supranuclear palsy, corticobasal degeneration, meso-limbo-cortical dementia and severe Azheimer's disease. In life, LBD is characterized by the association of parkinsonism and a dementia with deficits in attention, executive functions and visuospatial abilities. There are often fluctuations in alertness, sometimes amounting to transient unresponsiveness. And recurrent formed hallucinations with little or no affective component are common. In spite of these typical features, the distinction of LBD in the elderly may be very uncertain.

About 20% of all patients with PD develop dementia. The prevalence of diagnosed PD is overall about 1/1000, but the prevalence increases with age and reaches nearly 2% in the ninth decade. An undiagnosed pre-symptomatic PD is very much more common, so that pathological findings indicative of the disease are present in about 10% of the healthy population in the ninth decade[3]. Dementia in PD is more common in the elderly patient, and patients with dementia tend to be significantly older at the onset of their PD[4]. By contrast, early-onset PD tends to have a low incidence of dementia[5].

Patients who present with dementia and later develop typical PD are probably suffering from LBD, now categorized as one of the "Lewy body disorders".

Dementia associated with PD is therefore a common occurrence in clinical practice. A number of important and interesting questions arise from these facts. Has the dementia any specific clinical features that distinguish it from "senile" dementia of the Alzheimer type? Has the type of PD that is associated (perhaps at a late stage) with dementia any specific clinical features compared with the type of disease where dementia is uncommon? What is the relationship, if any, between treatment for PD and the development of dementia? What are the neuropathological correlates between PD and dementia? Are both phenomena caused by the same process?

CLINICAL FEATURES OF THE DEMENTIA ASSOCIATED WITH PARKINSON'S DISEASE

Cognitive testing in PD may be affected by a number of extraneous factors, including impaired motor function, medication or mood disturbance. In people with no associated disease, cognitive function can be compared with premorbid intelligence and the decline estimated. However, no validated method for estimating premorbid intelligence in PD has been developed. Depression is common in PD and may give a pseudodementia, relieved by antidepressant treatment. For these and other reasons, no generally accepted pattern of cognitive function has emerged as characteristic of PD and longitudinal studies are needed.

ORGANIC DISORDERS

The concept of subcortical dementia was originally introduced by Albert with reference to the dementia in the rare form of parkinsonism seen in progressive supranuclear palsy[7]. Subcortical dementia is characterized by forgetfulness, slowing of thought processes (bradyphrenia), apathy and impaired ability to manipulate acquired knowledge. This pattern of deficit is contrasted with diseases such as Alzheimer's disease, characterized by global memory impairment, aphasia, agnosia and apraxia. While much overlap seems to exist between these types of cognitive impairment, bradyphrenia, apathy and depression seem to characterize the dementia of PD. Thought-block is an early characteristic of the dementia and fluctuation of the cognitive impairment has been noted[8]. Visual hallucinations, often with little or no affective component, are common. Less common are paranoid delusional states.

Patients with PD and dementia show a treatment response for their parkinsonism that is inversely related to the severity of the cognitive changes[9].

DO SPECIFIC CLINICAL FEATURES OF PARKINSON'S DISEASE INDICATE THE LIKELIHOOD OF DEMENTIA?

Lieberman *et al.*[10] demonstrated that the dementia of PD was associated with a later age of onset, a poorer response to L-dopa and less abnormal involuntary movements and dose fluctuations in response to L-dopa. These findings have been confirmed[4,5,9] in later studies.

Tremor is less common as a presenting symptom in patients with PD associated with dementia, whereas dyspraxia of gait and

dyspraxias for hand movements are more common. Thus, a patient who has difficulty in performing the discrete finger movements used to test for bradykinesia may commonly show early cognitive changes.

The rate of progression of the PD is significantly greater in cases where dementia further affects management and survival. Patients with dementia tolerate drug treatment less well and tend to develop more persistent and severe toxic confusional states.

Thus, many authors accept that PD may exist in a late-onset form with certain characteristic clinical features and a relatively poor response to L-dopa where dementia is common. By contrast, there is a type of PD in which dementia is rare. The disease has an earlier onset and response to L-dopa is initially very good[12,13].

All drugs used in the treatment of PD carry a risk of provoking toxic confusional states and this reaction is more likely and more severe in patients with cognitive changes. Where therapeutic benefit from a drug is likely to be modest, there is a relative contraindication to the use of that drug in an elderly patient, particularly if they are showing cognitive changes. For this reason, the anticholinergic drugs are seldom recommended in geriatric practice[14].

Conversely, in patients with classical PD in middle life, where the prospect of cognitive impairment is small (but the risks of permanent response fluctuations to L-dopa are high) anticholinergic drugs are indicated in preference to L-dopa if disability can be satisfactorily controlled.

The fluctuation of the dementia already noted may suggest that the cognitive changes are related to drug therapy. This possibility should usually be investigated by dose reduction or withdrawal, but if no improvement occurs the patient need not be deprived of the physical benefits of the drug. Many elderly patients with mild cognitive changes tolerate L-dopa therapy with benefit and without any significant exacerbation of their mental impairment. Occasionally the administration of L-dopa in patients with dementia may provoke states of excitement with impulsive behaviour and aggravation of the dementia[15].

The synthetic dopamine agonists (bromocriptine, lisuride, pergolide, ropinirole) and the anticholinergics should be used only with great caution in the parkinsonian patient with dementia.

WHAT IS THE RELATIONSHIP, IF ANY, BETWEEN TREATMENT FOR PARKINSON'S DISEASE AND THE DEVELOPMENT OF DEMENTIA?

The two drugs in most widespread use for the treatment of PD are benzhexol and L-dopa (with decarboxylase inhibitor). We must examine the evidence concerning whether either of these drugs could be causing or accelerating dementia in PD.

Alzheimer's disease is known to be associated with a reduction in brain choline acetyltransferase, and anticholinergic drugs exacerbate the neural changes in this condition, but there is no evidence of permanent effects on higher mental function from these drugs in PD. Confusional states provoked by benzhexol recover with a timescale of usually less than 4 weeks. It is noteworthy that the use of a high-dose anticholinergic drug in the treatment of dystonias over many years is not associated with any cognitive changes.

However, studies of the prevalence of dementia in PD before the L-dopa era gave figures of 3.2–10%[16] or 851%[17], whereas since the introduction of L-dopa, the prevalence of dementia has risen to above 20%.

Like anticholinergics, L-dopa may provoke acute confusional states that recover when the drug is withdrawn. But withdrawal of L-dopa rarely alters the decline of mental faculties in parkinsonian patients with dementia. The duration of L-dopa treatment does not appear to correlate with the likelihood of mental impairment[18]. At the present time, the evidence is against L-dopa treatment causing or accelerating the dementia of PD.

WHAT ARE THE NEUROPATHOLOGICAL CORRELATES BETWEEN PARKINSON'S DISEASE AND DEMENTIA?

With the advent of staining techniques based on anti-ubiquitin immunocytochemistry[19] neuropathological correlates between PD and dementia showed that by far the commonest cause of dementia in this condition was diffuse LBD[20]. Previously parkinsonian dementia had been attributed to a supposed association between PD and Alzheimer's disease, but the new staining techniques showed that in PD without dementia the Lewy body was substantially confined to the brainstem, whereas in PD with dementia, diffuse cortical Lewy body formation was demonstrable.

By contrast, in Alzheimer's disease, neuronal loss in the nucleus basalis is associated with neurofibrillary tangles in this region and in the dorsal raphe nucleus. In cases of PD with dementia, scanty tangle formation may be seen in the hippocampus or neocortex, but with profuse cortical Lewy bodies not seen in Alzheimer's disease.

Senile plaques have been recommended as an important neuropathological criterion for the diagnosis of Alzheimer's disease[23]. But senile plaques are commonly seen in similar density to cortical Lewy bodies in cases with dementia[20], and thus fail to distinguish between the two conditions.

The dementia seen in some cases of PD is attributable to neuronal cell loss in the cortex associated with diffuse cortical Lewy body formation.

ARE BOTH PHENOMENA CAUSED BY THE SAME PROCESS?

Lewy body disease, in which parkinsonism is associated with dementia, is probably the second commonest cause of dementia after Alzheimer's disease[24]. The Lewy body is an intra-neuronal eosinophilic inclusion body that shows ubiquitin immunoreactivity, and is the pathological hallmark of PD.

Thus, PD is characterized by Lewy body formation in the brainstem and particularly in the substantia nigra[25]. In demented cases of PD there is cortical Lewy body formation as well and the severity of the dementia correlates with cortical Lewy body density[20]. It is therefore reasonable to conclude that the dementia and the parkinsonism are due to the same pathological process. The nature of this process is currently the subject of intense research.

LBD studied post mortem may show a variety of patterns. In the typical case, Lewy bodies may be distributed in the brainstem, diencephalon, limbic system and cortex, but in some cases Lewy bodies are confined to the brainstem and are few or absent in the cortex or limbic system. In these cases there are also no senile plaques, whereas where Lewy bodies are present in the cortex, senile plaques may also be seen.

Probably the most specific marker for the Lewy body is α-synuclein, and this protein has been associated in some families with autosomal dominant PD. The pathological process of Lewy body diseases may be partly genetic and seems to be independent from, but sometimes co-existent with, the pathological process of Alzheimer's disease. There is increasing interest in the genetic markers of PD and dementia, but it remains likely that there is an environmental trigger in genetically susceptible cases.

It has already been noted that parkinsonism with dementia is a form of PD that tends to have later onset than classical PD

without dementia. This suggests that the elderly cerebral cortex is vulnerable to the same pathological processes as the substantia nigra (and which lead to parkinsonism), whereas the younger cerebral cortex is relatively resistant, so that early-onset PD tends to be unassociated with dementia. The nature of this age-related vulnerability of the cortex is unknown, but it is of interest that age-related differential vulnerability to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) has been demonstrated in primates[26].

CONCLUSIONS

The dementia of PD is entirely distinct from the dementia of Alzheimer's disease. In PD dementia is associated with Lewy body formation in the cerebral cortex as well as in the substantia nigra; whereas in Alzheimer's disease neuronal loss and neurofibrillary tangle formation is characteristically in the dorsal raphe nuclei and nucleus basalis of Meynert.

The clinical features of the two forms of dementia are usually distinguishable. More difficult to distinguish clinically, especially in the earlier stages, are the two types of PD. In one the disease presents typically in middle life, progresses slowly, responds well to dopamine agonists and is not associated with dementia; whereas the other (diffuse Lewy body type) presents in late life, progresses more rapidly, responds less well to dopamine agonists and is associated with dementia. The clinical significance of making this distinction is to define prognosis and also to affect management, in particular the use of dopamine agonists and the management of dementia.

The cause of PD and of Alzheimer's disease remains unknown but there are promising lines of investigation related to the genetics and molecular biology of the Lewy body and the neurofibrillary tangle, respectively.

Clinical Criteria for Dementia with Lewy Bodies

I. G. McKeith

Newcastle upon Tyne General Hospital, UK

Why are diagnostic criteria for dementia with Lewy body (DLB) important? There are many reasons, but the most significant are to properly advise patients and carers, to minimize neuroleptic prescribing and possibly to effectively target cholinesterase inhibitor use. Also, since DLB is relatively common, it needs to be routinely excluded in the differential diagnosis of other dementia subtypes, particularly when a diagnosis of Alzheimer's disease (AD) is being considered. Several studies have now reported on either the sensitivity (proportion of cases positively identified) or specificity (proportion of negative cases correctly identified) of the International Consensus criteria for DLB, against neuropathological diagnosis. Most find "probable DLB" criteria to have a specificity 40.8, a figure comparable with the best clinical criteria for AD and Parkinson's disease (PD). High specificity means that when a diagnosis of probable DLB is made, it is likely to be correct. The more lenient "possible DLB" category should be useful as a screening tool for identifying cases in the clinic, although many false-positive diagnoses will be made.

Sensitivity rates for probable DLB are more variable and generally lower. This may in part be due to *retrospective* application of the criteria to case records in most of these studies. Spontaneous documentation of fluctuation and detailed psychiatric phenomenology in case notes is notoriously incomplete, leading some to conclude that inter-rater reliability for individual diagnostic items, especially "fluctuation", is unsatisfactory. Although a tighter operational definition, or a biological measure, of fluctuation would undoubtedly be useful, studies *prospectively* applying the DLB diagnostic criteria generally find inter-rater reliability for individual items (including fluctuation) and for a final diagnosis of DLB, to be acceptable (k40.6), allowing for diagnostic sensitivities 40.8 to be achieved.

Ancillary investigations will have an important future role in improving the accuracy of clinical diagnosis of DLB. FP-CIT SPECT brain imaging demonstrates a large reduction in dopamine transport to the striatum in DLB, and this may be apparent before extrapyramidal signs are manifest. Nigrostriatal dopaminergic depletion is only rarely seen in AD or vascular dementia. Relative lack of medial temporal lobe atrophy on CT/MRI is also characteristic of DLB compared to AD.

The Second International Workshop on DLB recommended that the Consensus criteria should continue to be used in their current format for recruiting cohorts of DLB patients for research studies and clinical trials. Depression and REM sleep behaviour disorder were suggested as two additional features supporting the diagnosis.

Accurate case detection will ultimately be best achieved by increasing the index of suspicion for a diagnosis of DLB, not only in dementia assessment clinics but also in any setting where elderly patients may present with delirium, movement disorder, falls or syncope. Perhaps we might do better to frame the next revision of the diagnostic criteria within a broader spectrum of Lewy body-related disorders or a-synucleinopathies, thereby acknowledging the links between PD, DLB and primary autonomic failure, and breaking down some currently unhelpful boundaries between psychiatry, neurology and geriatric medicine.

Subcortical Dementia

J. R. Burke

Duke University Medical Center, Durham, NC, USA

Health-care workers who evaluate older patients are frequently confronted with individuals who they suspect have dementia. Although it is often straightforward to determine whether an individual is demented, determining the etiology of the dementia can be difficult. Dementia is not a single disease, but a heterogeneous complex of disorders with the common finding of impairment in multiple cognitive domains. Fortunately, clues leading to a correct diagnosis can be obtained in the physical and mental status examination.

A heuristic device that can aid in the evaluation of patients with dementia is to divide diseases into two categories, based on whether the pathology is primarily cortical or subcortical[1]. Although the cortical/subcortical dichotomy has been questioned on pathologic grounds, there are clinical features that distinguish one group from the other. The prototypical cortical dementia is Alzheimer's disease (AD). Diseases that cause subcortical dementia include small vessel cerebrovascular disease, Parkinson's disease and Huntington's disease (Table 50b.1)[2].

Table 50b.1. Causes of subcortical dementia

Parkinson's disease	Small vessel cerebrovascular disease
Progressive supranuclear palsy	Spinocerebellar ataxias
Huntington's disease	Hydrocephalus
Multiple systems atrophy	Multiple sclerosis
Wilson's disease	HIV dementia
Frontal lobe dementia	Vasculitis

CLINICAL FEATURES OF SUBCORTICAL DEMENTIA

The cardinal clinical features of subcortical dementia are apathy, inattention and psychomotor slowing[1,3]. Patients with subcortical dementia typically appear apathetic. They have a blunted affect, poor personal hygiene and sloppy appearance. The patients are often aware of their cognitive deficit but appear unconcerned. In contrast, patients in the early stages of AD typically have normal affect, grooming and dress. Patients with AD who are aware of their deficit are typically quite concerned.

It is easy to become frustrated when interviewing a patient with subcortical dementia because the patient's inattention leads to frequent repetition of questions by the examiner. Surprisingly, sometimes minutes after a question is asked, patients with a subcortical dementia will respond with the correct answer. Patients with AD have normal attention.

Slowing is a key feature of subcortical dementia and one of the most obvious signs during the examination. Slowing occurs in multiple areas, including cognition (thought formulation, language generation and processing), sensation (processing of stimuli) and motor performance (bradykinesia). While forcing a patient to respond quickly impairs performance in both cortical and subcortical dementia, individuals with subcortical dementia benefit from being given more time to complete a task. Additional response time does not have a similar beneficial effect for patients with AD. The apathy, inattention and psychomotor slowing due to subcortical dementia can be difficult to distinguish from depression. Patients with AD do not demonstrate psychomotor slowing, unless they are also depressed.

The type of memory dysfunction differs between subcortical and cortical dementia. Impaired registration and retrieval characterize the memory deficit in subcortical dementia, while intact registration and rapid forgetting are seen in AD. To test registration and retrieval, a patient is asked to repeat a short list of words immediately after presentation (registration) and after a delay (retrieval). In subcortical dementia, the list may have to be presented several times before all items are registered. Registration is intact in AD patients. Patients with subcortical dementia and AD may retrieve a similar number of items, but if presented with a choice, the patient with subcortical dementia can distinguish between items that were presented and items that were not (recognition). AD patients are unable to distinguish between list and non-list items. Patients with subcortical dementia also benefit from hints to recall items (cueing), while AD patients do not.

Patients with subcortical dementia also frequently display deficits in multi-step tasks. They may perform each step of a task individually, but be unable to incorporate steps to solve the problem. For example, a patient may be able to calculate the number of nickels in $1.00 and the number of nickels in $0.35, but not the number of nickels in $1.35.

Behavioral disturbance can occur with either cortical or subcortical dementia, but apathy and depression are more common in the early stages of a subcortical dementia and may predate other cognitive problems. The cortical signs, aphasia, apraxia and agnosia, are lacking in subcortical dementia and suggest either AD or a focal process such as stroke, mass lesion or focal degeneration (e.g. primary progressive aphasia).

Motor signs, such as increased tone and bradykinesia, are common in subcortical dementia. Abnormal movements, such as tremor, chorea or dystonia, may also occur. Posture is often abnormal and patients may appear stooped or extended when standing. Gait problems include poor initiation, small step length and difficulty turning. AD patients do not demonstrate motor signs, abnormal movements or posture and gait abnormalities until the latter stages of dementia.

DISEASES CAUSING SUBCORTICAL DEMENTIA

Extrapyramidal Disorders

Parkinson's Disease (PD)

PD is a common cause of subcortical dementia and is diagnosed by the clinical findings of bradykinesia, tone abnormalities (rigidity and cogwheeling) and rest tremor. Almost all patients with PD can be shown to display cognitive slowing and other features of subcortical dementia, but only a subset progress to frank dementia[4]. Further complicating matters, some demented patients with PD develop a mixed cortical and subcortical dementia. At autopsy, patients with mixed dementia may exhibit pathologic signs of AD and PD or diffuse, intraneuronal Lewy bodies. The exact relationship between Parkinson's dementia, Lewy body dementia and AD is poorly understood[5].

Other parkinsonian syndromes are also associated with subcortical dementia. Progressive supranuclear palsy (PSP) can be distinguished from PD by limited voluntary vertical eye movements, absence of rest tremor, extended (rather than stooped) posture and lack of response to dopamine replacement[6]. Clinically significant dementia is more common in PSP than PD. Multiple systems atrophy (MSA) is another parkinsonian syndrome that can be associated with subcortical dementia. Patients with MSA have a variable combination of parkinsonism, cerebellar ataxia, corticospinal tract abnormalities and/or autonomic dysfunction[7].

Huntington's Disease (HD)

HD is an autosomal dominant inherited neurodegenerative disease characterized by psychiatric abnormalities, chorea and subcortical dementia[8]. The earliest symptoms of HD are often psychiatric and demented HD patients display the classic features of subcortical dementia. HD is caused by pathologic expansion of a CAG repeat in the huntingtin gene. A blood test is commercially available to detect the causative mutation.

Cerebrovascular Disease

The location of infarcted brain tissue in a stroke determines its clinical features. Strokes involving the cerebral cortical gray matter will cause cortical signs such as aphasia and apraxia. Subcortical dementia occurs when infarction involves the deep gray matter nuclei (e.g. basal ganglia and thalamus) and/or the periventricular white matter[9]. For dementia to develop, damage must be bilateral and multifocal. Small vessel strokes can be caused by lacunar infarction or Binswanger's disease. Lacunar strokes occur when small intracerebral penetrating blood vessels are occluded and Binswanger's disease is the result of chronic white matter ischemia. Risk factors for small vessel cerebrovascular disease include cigarette smoking, hypertension and diabetes mellitus. Patients with small vessel cerebral infarction may not experience any traditional stroke-like episodes and deny a step-wise decline in cognitive function. The physical examination will, however, demonstrate focal neurologic signs, including pseudobulbar palsy, hyper-reflexia and pathologic reflexes, such as the Babinski sign. CT or MRI is useful in demonstrating small vessel strokes in patients with suspected subcortical dementia.

Miscellaneous Causes

Multiple sclerosis (MS) and HIV infection can cause subcortical dementia. These diseases are often suspected when confronted by a young person with dementia, but should also be considered in older patients. Dementia is usually a late finding in MS and is typically associated with other neurologic signs, including eye movement abnormalities, motor findings, sensory symptoms and/or cerebellar deficits. The presence of cerebellar ataxia and subcortical dementia is also seen in patients with spinocerebellar ataxias (SCA). There are a large number of different diseases that present as SCA and the diseases may be sporadic or inherited[10]. Magnetic resonance brain imaging of patients with advanced SCA will show cerebellar and/or brainstem atrophy. Genetic testing is available for many of the inherited forms of disease.

Hydrocephalus can cause subcortical dementia. Hydrocephalus may occur in the elderly without obvious lesions obstructing cerebrospinal fluid (CSF) flow and with normal CSF pressure [normal pressure hydrocephalus (NPH)]. Brain imaging of patients with NPH shows enlarged ventricles and widely patent intraventricular foramina. The clinical signs of NPH include the well-known triad of subcortical dementia, urinary incontinence and gait apraxia. CSF shunting of patients with NPH can result in significant improvement, but is typically unsuccessful if the dementia is long-standing or far-advanced. Other potentially treatable causes of dementia can also present, with a subcortical pattern including chronic infection and vasculitis.

Frontal lobe dementia presents as a classic subcortical dementia, despite the fact that the pathology is located in frontal cortical neurons. The subcortical–frontal neuronal pathways mediate many of the features of subcortical dementia, including apathy, inattention, bradykinesia and problems with planning[3,11]. It is not surprising that damage to the subcortical nuclei, connecting white matter tracts or frontal neurons, present with a similar clinical phenotype. Other causes of frontal lobe damage can also cause a "subcortical" dementia, such as trauma, infarction, tumor or psychiatric disease.

CONCLUSION

Dividing the clinical presentation of patients with dementia into cortical and subcortical groups can be useful as a first attempt to identify the etiology of dementia, but this approach has limitations. Dementing diseases rarely cause purely cortical or subcortical pathology. Strokes can involve both white and gray matter. AD can cause degeneration in subcortical nuclei or frontal cortex and clinically resembles a subcortical dementia. Analogously, the pathology of frontal lobe dementia causes cortical neurons to degenerate, but the clinical profile is subcortical. Depression can further confuse the clinical picture by making a cortical dementia have subcortical features, leading to inaccurate diagnosis. The classical distinction between subcortical and cortical dementia is also less clear in patients with advanced dementia, because the clinical patterns tend to merge. Despite these problems, recognition of subcortical features can increase one's suspicion of unusual causes of dementia and lead to increased accuracy of diagnosis and, potentially, treatment.

Early-onset Dementias

Gandis Mazeika

Duke University Medical Center, Durham, NC, USA

The early-onset dementias are a heterogeneous group of neurodegenerative diseases with onset generally defined as prior to age 65. Research into these diseases has suffered from ascertainment bias, inconsistency in definitions, small numbers and inaccuracies associated with retrospective review of charts and death records. However, clinically useful information has gradually emerged over more than 60 years of study.

Liston reviewed the topic in 1979 and contributed a series of 50 cases[1,2]. Despite several significant advances in the field since that time, most notably the discovery of the presenilin genes, his review continues to be an excellent starting point in understanding this group of diseases.

EPIDEMIOLOGY

Early-onset dementia represents approximately 5–10% of all dementias seen by health caregivers.

The relative frequency of common dementia subtypes in early-onset dementia roughly parallels that for senile dementia. The most prevalent form of dementia is Alzheimer's disease (AD), followed by vascular dementia (VaD). In countries with a high rate of alcohol use, alcoholic dementia has a frequency roughly equal to vascular dementia. The frequency of less common dementing illnesses, such as inborn errors of metabolism and chronic CNS infection, is expected to be higher than in older age groups; however, epidemiological studies are lacking.

Estimates of annual incidence for early-onset AD (EOAD) vary from 2.4 to 22.6/100 000[3–7]. One study found a point prevalence of 34.6/100 000 with a 5 year survival of 68%. Median survival was estimated as 8.1 years in another study. These estimates suggest a more aggressive course for EOAD compared with the senile variant. Most studies support increased risk among females for PSAD, with a relative risk of 1.0–1.7.

Only a few epidemiological studies have attempted to include other etiologies of dementia. Two studies from Scotland varied widely with respect to relative frequencies of PSAD and vascular dementia[3,6]. One study found comparable frequencies, while another found the frequency of vascular dementia to be about 20% that of PSAD. In the latter study, of 114 patients, 60 had PSAD, 13 had vascular dementia, 14 had alcohol-related dementia, 25 had overlapping diagnoses and two had other diseases.

EARLY-ONSET ALZHEIMER'S DISEASE

EOAD differs from senile onset AD in several respects, including patterns of inheritance and disease course[8]. While the majority of cases of EOAD are sporadic, there is a significantly increased frequency of familial clusters in comparison to senile AD[9]. These clusters have facilitated linkage analysis, leading to the identification of a number of mutations in several genes. So far, three genes have been linked to familial EOAD (Table 50c.1). It is estimated that approximately 50% of familial cases of EOAD can be attributed to known mutations, suggesting that other genes yet to be identified are involved as well.

Table 50c.1 Genes linked to familial EOAD

Gene	Chromosome	Known mutation as of 1999
Amyloid precursor protein (APP)	21	5
Presenilin 1	14	45
Presenilin 2	1	2

The mutations listed in Table 50c.1 all result in increased abnormal cleavage of APP, ultimately leading to production of amyloid plaques. The inheritance pattern for mutations in all three genes is autosomal dominant with high penetrance. No practical screening tests are currently available.

The apolipoprotein E (ApoE) gene on chromosome 19 has been identified as an important susceptibility gene for EOAD. Three naturally occurring allotypes of ApoE are known, ApoE 2, 3 and 4. Individuals homozygous for ApoE 4 have approximately twice the relative risk of developing AD as individuals homozygous for ApoE 3. Conversely, individuals with one or two copies of ApoE 2 have approximately half the risk for EOAD as individuals homozygous for ApoE 3. Risk appears to be greatest in individuals developing cognitive impairment between 60 and 65 years of age and declines in older age groups.

The role of ApoE in AD is poorly understood and is the topic of intensive research. In addition to its role in AD, homozygosity for ApoE 4 has been found to be a risk factor for poor outcome following stroke. Thus, ApoE is thought to possibly play a role in mediating inflammatory responses in the brain.

Age at onset of AD has been shown to be an important determinant of disease course and clinical presentation, with more rapid cognitive and functional decline observed in EOAD. On neuropsychological testing, individuals with EOAD score significantly worse on attentional items compared with senile AD. These observations have suggested the possibility that EOAD may be a different clinical entity than senile AD.

VASCULAR DEMENTIA

Little information exists regarding early-onset vascular dementia (EOVD), although the relative frequency in some areas, notably Japan, appears to be equal to EOAD. Risk factors are similar to senile vascular dementia and include hypertension, diabetes mellitus, smoking and hypercholesterolemia. As with EOAD, there is an increased prevalence of familial clusters in EOVD, most of which can be attributed to homocysteinuria, although other inherited coagulopathies may play a significant role. There is probably a considerable overlap between cases of EOAD and EOVD. Readers interested in additional information about the diagnosis of AD or VaD are referred to reviews by Gersing *et al.*[12] and by Doraiswamy *et al.*[13]

APPROACH TO DIAGNOSIS

There are perhaps several hundred disorders with dementia as a clinical feature. Most of these disorders are quite rare. This diversity in etiology poses a significant challenge to the clinician. For example, a case report of two patients with clinically similar features found one to have EOAD and the other to have adult onset metachromatic leukodystrophy[10].

The following general guidelines, although not exhaustive, are intended as an aid in the work-up of patients presenting with cognitive impairment at age 65 and younger:

1. History of present illness:
   (a) A gradual insidious course is suggestive of EOAD.
   (b) Cognitive decline in association with a stroke or ‘‘spells’’ raises the index of suspicion for EOVD.
   (c) A lifelong history of underachievement, childhood delay in milestones or difficult pregnancy or delivery is suspicious for an inherited disorder affecting cognition.
2. Ask about risk factors for less common dementias:
   (a) Exposure to toxins, including carbon monoxide, solvents, pesticides, heavy metals.
   (b) History of childhood encephalitis or meningitis.
   (c) History of multiple concussions.
   (d) History of malabsorption, diarrhea or significant change in diet.
   (e) Parental age at birth.
   (f) Detailed history of alcohol and drug use.
   (g) AIDS risk factors.
3. Past medical history:
   (a) Search for potentially reversible causes of dementia:
      (i) Thyroid disease.
      (ii) Epilepsy.
      (iii) Syphilis.
      (iv) Pernicious anemia.
      (v) Lupus, sarcoidosis, other CNS inflammatory diseases.
      (vi) Cancer.
      (vii) Hepatitis.
4. Search for illnesses that may mimic dementia:

Table 50c.2 Checklist for neurological examination in dementia diagnosis

Dementia associated with neuropathy
1. Hypothyroidism
2. Nutritional disorders, especially B_{12} deficiency
3. Vasculitis, especially Sjogren’s syndrome, SLE
4. Exposure to solvents and alcohol
5. Multi-infarct dementia associated with diabetes
6. HIV
7. Neurosyphilis
8. Lyme disease
9. Metachromatic leukodystrophy
10. Adrenoleukodystrophy

Dementia associated with hemiparesis
1. Multi-infarct dementia
2. Mitochondrial encephalomyelopathy with stroke-like episodes (MELAS)
3. Vasculitis from various causes
4. Masses in the brain, including tumors, vascular malformations, hematomas, abscesses, etc.
5. Complex partial epilepsy
6. Amyotrophic lateral sclerosis

Dementia associated with tremor or rigidity
1. Early-onset Parkinson’s disease
2. Multisystem atrophy
3. Spino-cerebellar degeneration
4. Multi-infarct dementia, especially with involvement of the basal ganglia
5. Huntington’s disease
6. Wilson’s disease
7. Progressive supranuclear palsy
8. Hallevorden–Spatz disease
9. Manganese poisoning
10. Post-encephalitic dementia
11. Multiple sclerosis
12. Carbon monoxide poisoning
13. Cryptococcal meningitis
14. Dementia pugilistica

Dementia associated with nystagmus and/or ataxia
1. Wernicke’s encephalopathy
2. Spino-cerebellar degeneration
3. Alcoholic dementia
4. Paraneoplastic encephalopathy
5. Hydrocephalus

Dementia associated with dysautonomia
1. Multisystem atrophy
2. Multi-infarct dementia with diabetes
3. Parkinson’s disease

Dementia associated with myoclonus
1. Early-onset fronto-temporal dementia
2. Creutzfeldt–Jakob disease
3. Post-anoxic encephalopathy
4. Autoimmune thyroiditis
5. Whipple’s disease

Dementia associated with epilepsy
1. Metastatic brain lesions
2. Cryptococcal meningitis
3. Dentato-pallido-luysian atrophy
4. Anti-epileptic drug-related encephalopathy

Dementia associated with eye movement abnormalities
1. Multiple sclerosis (intranuclear ophthalmoplegia)
2. Progressive supranuclear palsy (impaired vertical gaze)

Dementia associated with myopathy
1. Myotonic dystrophy
2. Hypothyroidism
3. Diabetes mellitus

Dementia with variable physical findings
1. Primary HIV dementia
2. PML
3. ADEM
4. Metabolic causes, e.g. hypothyroidism, hypercalcemia, Addison’s disease
5. Dementia with Lewy bodies

Dementia with a positive family history
1. Familial AD (Presenilin 1 and 2 mutations)
2. Inborn errors of metabolism
3. Huntington’s disease
4. Mytotonic dystrophy

(a) Sleep disorders, including sleep apnea and narcolepsy.
(b) Depression, PTSD, anxiety disorders.
(c) Ongoing occult substance abuse.
(d) Subacute delirium.

5. Review medications:
   (a) Long-term anticholinergic, neuroleptic and/or anticonvulsant use is associated with cognitive impairment.
   (b) Overaggressive treatment of hypertension can result in hypoxic/ischemic encephalopathy.
6. Family history:
   (a) Strokes or MI at an early age suggests coagulopathy or familial hypercholesterolemia.
   (b) Strong family history of diabetes mellitus should prompt search for occult diabetes.
   (c) Early-onset dementia without other neurological findings suggests familial EOAD.
   (d) Amyotrophic lateral sclerosis has a familial association with frontotemporal dementia.
7. Mental status examination is intended to reveal the pattern of cognitive impairment and should minimally include:
   (a) Mini-Mental Status Examination.
   (b) Additional tests for retrieval, such as list generation.
   (c) Additional tests for attention, such as asking to recite months in reverse.
   (d) Additional tests for visuospatial function, such as drawing a transparent cube.
   (e) Tests of motor praxis, such as demonstrating untying and tying a shoelace.
   (f) Tests of frontal lobe function, such as Luria sequencing, visual go–no go testing and general assessment of judgment.
8. Thorough neurological examination:
   (a) See Table 50c.2.
9. Head imaging:
   (a) Some form of head imaging should probably be performed in all cases of early-onset dementia, especially if focal neurological findings are present.
      (i) While CT is readily available and inexpensive, MRI is superior in imaging the posterior fossa and in distinguishing between demyelination and edema in white matter lesions.
10. Laboratory studies:
    (a) Should be tailored to the findings on history, mental status and physical examinations.
       (i) The interested reader is referred to an excellent and exhaustive review of rare dementia syndromes by Reichmann and Cummings[11].
    (b) All patients should be tested for blood count, electrolytes, liver panel, albumin, B_{12}, folate, VDRL, sedimentation rate.
       (i) While the yield of these investagations is low, their cost is low as well, and they screen for reversible causes of dementia.
    (c) ApoE genotype is reasonable in cases suspicious for EOAD, especially if there is no significant family history.

Creutzfeldt–Jakob Disease and Other Degenerative Causes of Dementia

T. F. G. Esmonde

Royal Victoria Hospital, Belfast, UK

The following disorders may have dementia as a prominent part of the illness, but overall they are not common in clinical practice. Rarely is it possible to differentiate them on the basis of the form that the dementia takes, but other features can make them sufficiently distinctive to be worthy of description.

CREUTZFELDT–JAKOB DISEASE (CJD)

This disorder was first described in 1921[1,2], when an unusual fatal neurological illness in six cases was associated with a microscopic spongy appearance of the brain at post mortem. It is a rare, rapidly progressive dementing illness, affecting both sexes, with an onset usually after the age of 55, the exceptions being those cases associated with transmission from human-derived products or tissues, or new variant CJD. The presenting features include myoclonus, cortical blindness, pyramidal/extrapyramidal/cerebellar features and akinetic mutism. It is universally fatal, with an illness duration that rarely exceeds 6 months. No cause has been found, but the existence of similar neurological illnesses in other mammals also with spongy appearances of the brain has led to much research.

In the 1950s, a disease known as kuru was discovered in a tribe that practised cannibalism in the New Guinea highlands. This had many clinical and pathological similarities to CJD, and in 1968 the disease was transmitted to monkeys by intracerebral inoculation of extracts of kuru brain[3]. Kuru was felt to have been transmitted to other members of the the tribe through their practice of eating part of the remains of a previous kuru victim, especially the brain.

Scrapie is a spongiform encephalopathy of sheep that has been recognized for over 250 years and has been known to be transmissible to other sheep by natural means, both vertically and horizontally, since the 1930s. In 1986, cattle were also found to have developed a bovine spongiform encephalopathy (BSE)[4]. The theory advanced to account for this was that they had been exposed to scrapie through the consumption of rendered sheep remains as part of their diet.

An altered form of a normal brain protein has been found in cases of spongiform encephalopathy in both man and animals, which shows resistance to protease digestion and is known as protease-resistant protein (PrP) or "prion" protein[5]. The normal variant is encoded for by a gene on chromosome 20 in humans[6]. Already a number of mutations of this gene in cases of CJD have been discovered[7], and familial cases are invariably associated with abnormalities of the gene. Homozygosity for methionine at the site of a common polymorphism at codon 129 on the PrP gene is found with twice the normal incidence in cases of sporadic CJD[8], whereas valine homozygosity incidence is higher in cases associated with human growth hormone administration.

The possibilities of the disease being due to a viral or immunological process has largely been discounted, and current opinion is focusing on somatic mutation in the PrP gene as a possible cause.

The incidence of CJD, with few exceptions, is remarkably constant worldwide, at approximately 0.5–1/million population/year. Clustering of cases has been recognized[9] and this is thought to represent genetic susceptibility, rather than the presence of an environmental factor. Sporadic CJD is not felt to be due to transmission from consumption of or contact with animal products[10]. Cases have occurred in recipients of human-derived products such as growth hormone, gonadotrophin, corneal grafts and dura mater grafts, and following neurosurgical procedures[11–14]. Notable amongst these have been cases in patients who received human pituitary extracts, in whom pathologically confirmed CJD was manifest 10–20 years later, suggesting a prolonged "incubation period" before the disease occurs.

Diagnosis of CJD can only be made with certainty at post mortem or by brain biopsy. However, the diagnosis has been confirmed by tonsillar biopsy in suspected cases[15], although this technique is not widely recommended in view of the possible risk to operators[16]. The finding of elevated levels of cerebrospinal fluid levels of S100 and 14-3-3 proteins is relatively specific for suspected CJD, although raised levels are also found in encephalitis[17].

The rapidity with which the dementia develops, with global cortical and subcortical components as well as the specific signs mentioned earlier, should avoid confusion with other causes of dementia. The electroencephalogram (EEG) often shows a typical appearance of generalized repetitive triphasic complexes, with virtual abolition of background rhythms, but this feature is not invariable, often occurring late in the course of the illness. Its absence in no way excludes the disorder. There is almost always a slowing of cortical rhythms into the delta range. Computed tomography (CT) scan is usually normal, but is useful to exclude other conditions. Magnetic resonance imaging (MRI) can show non-specific high signal on T2-weighted images in the basal ganglia in some cases.

There is no treatment available, although there have been isolated case reports of slowing of the rate of progression of the disorder with amantadine[18].

NEW VARIANT CJD

The first cases of new variant CJD appeared in 1995, when individuals under the age of 40 years developed a rapidly progressive dementing illness, and pathological analysis at post mortem confirmed the typical features of spongiform encephalopathy[19]. There were a number of important differences to typical sporadic CJD, however:

1. Many of the cases presented with features of a psychiatric disorder, such as anxiety, depression or hysteria.
2. The development of the dementia was more slowly progressive than in typical cases of CJD.
3. The typical changes of triphasic complexes on the EEG were lacking.
4. Brain microscopy revealed far more extensive PrP-positive plaques.

The evidence that these cases may be directly linked to BSE in cattle is compelling in that the PrP protein in these cases is biochemically very similar to that found in cases of BSE, and the incubation time of transmitted cases in transgenic mice expressing the human PrP gene is identical to that of transmitted BSE cases[20]. Up to September 2001, 107 cases had been described, one of which was in an elderly man aged 74.

MULTISYSTEM ATROPHY (SHY–DRAGER SYNDROME), PROGRESSIVE SUPRANUCLEAR PALSY (PSP) (STEELE–RICHARDSON–OLSZEWSKI SYNDROME), DENTATOPALLIDO–LUYSIAN ATROPHY AND OLIVOPONTOCEREBELLAR ATROPHY (OPCA)

Dementia is not an invariable accompaniment of any of the above, but thorough cognitive testing will often reveal deficits, especially in late cases. The dementia may be of frontal lobe type or sub-cortical but not severe, and may be masked by other clinical features that are more prominent[21].

Nomenclature of the above conditions is subject to debate. Extrapyramidal features are seen in most, although a clinical presentation with prominent cerebellar features tends to result in a patient being labelled as OPCA and pronounced autonomic failure as Shy–Drager syndrome, but the pathological changes of cell loss and gliosis in all are similar and may also be present in the same sites, although to varying degrees. Only in PSP is there a clearly distinct clinical presentation and histological appearance.

The early signs in all the above conditions are usually rigidity in muscle tone, bradykinesia of movement and postural instability. The signs are usually bilateral and progress over months and years.

In PSP, first described in 1964[22], there is characteristically a loss of conjugate voluntary eye movements, beginning with vertical gaze. The range of eye movement is improved if the patient is made to fixate on a target and the head moved. Upper motor neurone limb signs are common, and dystonic posturing of neck muscles resulting in extension is often seen. Reduction in verbal fluency is a prominent feature of the condition, and it has been postulated that this is due to interruption of fronto-basal circuitry[23]. The condition is confirmed pathologically by the finding of neuronal loss, neurofibrillary tangles and gliosis primarily affecting the subthalamic nucleus, globus pallidus, dentate, substantia nigra, locus coeruleus, periaqueductal grey matter and other brainstem nuclei.

Multisystem atrophy (MSA) results in a degenerative process affecting neurones throughout the central nervous system (CNS) and thus the signs may be widespread, with involvement of corticospinal tracts and especially the autonomic system. Diagnosis is usually clinical and may be strongly suspected when there are additional signs, such as laryngeal stridor or denervation of the urethral sphincter on electromyography.

Dentatorubral-pallido-luysian atrophy is an autosomal dominant disorder that has been found to be linked with a trinucleotide repeated on the B37 gene of chromosome 12. The clinical features include seizures, chorea, dementia, ataxia, mental retardation and psychiatric disease. Abnormalities are seen in the subcortical white matter.

Other investigations in this group of conditions are usually normal, although evidence of cortical atrophy may be present in late cases on the CT scan, and a case has been made for the differentiation of PSP from other causes of extrapyramidal syndromes and dementia by subtle findings on CT[24].

The parkinsonian features in these disorders are often resistant to treatment with conventional anti-parkinsonian drugs. In the case of MSA, L-dopa therapy can exacerbate symptoms of postural hypotension due to the coexistent autonomic neuropathy. The disorders are therefore treated along supportive lines, although MSA may require more specific drug therapy, directed at features such as postural hypotension.

In all the above disorders, depression can be a common accompanying symptom, as patients are aware of the restriction in activity caused by the disease. This may require separate treatment.

As mentioned earlier, a dementing illness may also occur, especially in the later stages. However, this may be overlooked if poor performance on a task is attributed to slowness of response or the effects of drug therapy.

MOTOR NEURONE DISEASE

This disorder, which primarily causes loss of both upper and lower motor neurones, can also be associated with a dementia. Dementia is detectable in approximately 5% of cases, although its existence may be obscured if the patient is rendered anarthric and paralysed. It may preceded the onset of the typical signs of motor neurone disease in about 50% of cases, and is more common in those with a bulbar onset or in familial cases. Myoclonus has been noted in up to 15% of cases and this is probably what has been responsible for the confusion with Creutzfeldt–Jakob disease—with many of these cases being previously labelled as the "amyotrophic form of CJD", although the other clinical features of CJD, the typical EEG findings and laboratory transmission to animals, were lacking[25]. The dementia is typically "frontal" in type, with deficits in attention, learning, naming, insight and judgement[26].

ALS may also occur in association with both parkinsonism and dementia, with the dementia being indistinguishable from that occurring in Alzheimer's disease. The age of onset was almost the same for the parkinsonism, ALS and dementia, indicating that they are probably of the same aetiology.

The studies in Guam[27] have shown the development of a parkinsonism–dementia–ALS disease on exposure of individuals to the toxins from the cycad plant. In the review by Hudson[28], it is proposed that this link between the three modes of presentation may indicate that the disorders may be variants of the same disease and not unique to Guam.

NORMAL PRESSURE HYDROCEPHALUS

The title of this condition is a misnomer, as the cerebrospinal fluid (CSF) pressure is raised, but only intermittently, to produce what are known as "B" waves on continuous CSF pressure recordings. However, classic symptoms of raised intracranial pressure are

absent, the patient presenting with a triad of symptoms comprising dementia, gait dyspraxia and urinary incontinence. Cerebral atrophy is seen on CT scan, but the condition may be suspected when the ventricles are disproportionately large in comparison with the degree of sulcal widening. Unfortunately there is no reliable diagnostic test, as evidenced by recent reports in the literature[29]. Some claims have been made for isotope cisternography, which shows delayed passage of radioactivity from the ventricles to the area surrounding the cerebral convexities. Treatment is by the insertion of a CSF shunt, and in some cases this has even been used as the definitive diagnostic test. No cause has been found to account for the condition, although in some cases a ‘‘secondary’’ form is recognized as being due to previous meningeal inflammation or head injury and subsequent impairment of CSF uptake.

POST-TRAUMATIC DEMENTIA

Dementia pugilistica in boxers presents as a progressive neurological disease with involvement of pyramidal, extrapyramidal and cerebellar systems, in addition to memory loss and personality change. The onset may be many years after the cessation of a boxing career. The pathological appearances resemble those of Alzheimer’s disease, but neurofibrillary tangles predominate, with an absence of plaques[30].

HUNTINGTON’S DISEASE

This autosomal dominant inherited condition, with an onset usually after the age of 30 and rarely after the age of 70, has choreiform movements and dementia as its most common presenting features. Diagnosis can now be confirmed by analysing the huntingtin gene on chromosome 5 for CAG triplet repeats in excess of 35. Atrophy of the caudate nucleus may be seen in typical cases on CT or MRI scan. The dementia does differ from that of Alzheimer’s disease by virtue of the fact that there is more difficulty with tests of letter fluency and the copying of geometric features[31], indicating that the dementia is of the subcortical type.

FAMILIAL SPASTIC PARAPARESIS, OR SPINOCEREBELLAR ATROPHY ASSOCIATED WITH DEMENTIA

These conditions are considered together as both may produce a dementing-type illness which is in itself indistinguishable from other forms of dementia, but is set apart by the presence of other signs, such as a spastic paraparesis or a cerebellar syndrome. In both, the dementia advances only slowly, and may only be a minor feature of the illness, although recent work has shown that the cognitive impairment may be subclinical in some kindreds and overlooked with routine clinical screening tests[32].

PROGRESSIVE SUBCORTICAL GLIOSIS

This condition, described in 1967, presents as a dementing process with subcortical features and may mimic Alzheimer’s disease. Infrequent findings are signs of extrapyramidal involvement, and cases with supranuclear gaze palsy have been described[33]. The clinical course extends over years, often with a final akinetic mute stage. The cardinal pathological feature is intense gliosis and astrocytic hyperplasia affecting the subcortical structures of the thalamus, basal ganglia, brainstem grey matter and ventral horns of the spinal cord.

CORTICO-BASAL DEGENERATION

The more prominent signs of extrapyramidal dystonias, cortical sensory loss, dyspraxia, myoclonus (often focal) and the ‘‘alien hand’’ sign, tend to obscure a slowly developing dementia which is usually cortical in nature. The presence of ideomotor dyspraxia may help to distinguish this extrapyramidal syndrome from disorders such as PSP[34]. The mean age of onset in a series of 15 patients was 60 years[35]. No investigation is diagnostic, and confirmation of the diagnosis is by finding nerve cell loss and gliosis in the frontoparietal cortex and extrapyramidal system.

DEMENTIA LACKING SPECIFIC HISTOLOGICAL FEATURES

As well as being without specific histology, the pattern of dementia is unremarkable, being of a frontal lobe type more closely resembling Pick’s disease, with many cases also showing extrapyramidal features. The pathological features are cortical vacuolation and astrocytosis in the deeper layers, without neurofibrillary tangles, plaques or Pick or Lewy bodies.

Frontotemporal Dementia (Pick's Disease)

John R. Hodges

MRC Cognition and Brain Sciences Unit, Cambridge, UK

"Frontotemporal dementia" is the term currently preferred to describe patients with focal cortical atrophy involving the frontal and/or temporal lobes. Pathologically, such patients show severe neuronal loss, spongiosis and gliosis, and in a minority of cases classic argyrophilic, tau-positive intraneuronal inclusions are present (Pick bodies). The hallmark changes of Alzheimer's disease are virtually always absent[1].

One of the most exciting developments in the past decade has been the discovery of mutations in the tau gene on Chromosome 17 in some families with dominantly inherited FTD[2], although it should be stressed that most cases are sporadic. Clinically, FTD patients present with one of three major syndromes, which reflect the initial locus of pathology: dementia of frontal type, semantic dementia and progressive non-fluent aphasia[3]. It should be noted that each of these syndromes can be associated with motor neurone disease and a full neurological evaluation should also be included, especially in rapidly progressive cases and if bulbar symptoms develop[4].

Patients with FTD present below the age of 65 and there is an equal sex distribution. Although rare, FTD is the second commonest cause of dementia in the presenium (after Alzheimer's disease)[5]. In Cambridge we have studied approximately 100 cases with FTD; the rarest syndrome is non-fluent progressive aphasia, the other two account for approximately 40% of cases each. The average survival from diagnosis is, on average, 10 years. In our experience, patients with the frontal form of the disease progress at the slowest rate, semantic dementia cases have a more rapid course and those with motor neurone disease-associated FTD rarely survive more than 2 years.

DEMENTIA OF FRONTAL TYPE (DFT) (FRONTAL VARIANT FTD)

The onset of symptoms is insidious and insight is lacking. Relatives complain of a change in personality and behaviour: disinhibition, poor impulse control, antisocial behaviour, stereotypical features (e.g. insisting on eating the same food at exactly the same time daily, cleaning the house in precisely the same order or the use of a repetitive catchphrase) and a change in appetite and food preference towards sweet food are the features that best discriminate FTD from Alzheimer's disease. They reflect the early involvement of the orbitobasal frontal cortex[6,7]. Apathy is also very common but non-specific. Deficits in planning, organization and other aspects of executive function are universal as the disease progresses to involve the dorsolateral prefrontal cortex. Major depression and psychosis are rare.

A major advance in the area has been the development of a semi-structured carer interview, the Neuropsychiatric Inventory, which appears to be able to differentiate patients with FTD and AD[8].

Neuropsychological Findings

Some patients show clear-cut cognitive deficits at presentation but most traditional "frontal executive" tasks are sensitive to dorsolateral, rather than orbitobasal frontal, dysfunction; among the most useful are the Wisconsin Card Sorting Test and verbal fluency (i.e. the generation of words beginning with a given letter of the alphabet). Recently, quantifiable tasks involving decision-making and risk-taking and better able to detect orbitobasal frontal function have been developed[9].

Memory is relatively spared: orientation and recall of personal events is good but performance of anterograde memory tests is more variable, and patients tend to do poorly on recall (as opposed to recognition)-based tasks. A reduction in spontaneous conversation is common, but patients with DFT perform well on tests involving picture naming and other semantically-based tasks. Visuo-spatial abilities are strikingly preserved, particularly when the organization aspects are minimized: the Rey figure test is often copied poorly due to impulsiveness and poor strategy[10].

Simple cognitive screening tests, such as the Mini-Mental State Examination (MMSE), are unreliable for the detection and monitoring of patients with DFT, who frequently perform normally even when requiring nursing home care[11].

SEMANTIC DEMENTIA (TEMPORAL LOBE VARIANT FTD)

Patients with this variant of FTD present with a progressive fluent aphasia but the underlying cognitive deficit is a breakdown in semantic memory[3,12]. Semantic memory is the term applied to the component of long-term memory which contains the permanent representation of things in the world, including objects, words and people. It is the database which gives meaning to our sensory experiences.

Patients complain of "loss of memory for words". Although aware of their shrinking expressive vocabulary, patients are strangely oblivious to their impaired comprehension. Since the grammatical and phonological structure of language remains intact, the changes are relatively subtle, at least in the early stages. Patients with predominant right-sided atrophy may present with difficulty recognizing faces (prosopagnosia), at first affecting less commonly encountered people but with time severe prosopagnosia

develops: in contrast to the true modality-specific prosopagnosia, which occasionally complicates right occipitotemporal strokes, the deficit in semantic dementia is cross-modal, so that patients are also impaired in the identification of names and voices[13].

In contrast to Alzheimer's disease, patients with semantic dementia are well orientated and have good episodic (day-to-day and autobiographical) memory, although recent studies have shown that the preservation applies only to recent memories. That is to say, they show a reversal of the temporal gradient found in amnesia and Alzheimer's disease[14].

Behavioural changes may be slight at presentation but with time features identical to those seen in DFT emerge and may be striking in patients with right-sided disease[15].

Neuropsychological Findings

The impairment of knowledge is most apparent on tasks requiring a verbal output, such as category fluency tests (in which subjects are asked to produce as many examples as possible from defined semantic categories, such as animals, within 1 minute), picture naming and the generation of verbal definitions to words and pictures. The pattern of errors reflects a loss of fine-grained knowledge, with preservation of superordinate information: on naming tasks, naming errors are initially category co-ordinates (''elephant'' for hippopotamus), then with time prototype responses emerge, so that all animals are called ''dog'', then eventually they are simply called ''animal''. Single-word comprehension is also affected, as judged by tasks such as word–picture matching or synonym tasks (e.g. which of the following is the odd one out, ''pond, lake or river''). Non-verbal semantic knowledge is less easy to assess, but the Pyramids and Palm Trees Test in which the subject is asked to judge the semantic relatedness of pictures, invariably reveals deficits[10,16].

In contrast to the profound semantic deficit, other aspects of language competency (phonology and syntax) are strikingly preserved. Although able to read and spell words with regular spelling-to-sound correspondence, virtually all cases have difficulty in reading and spelling irregular words (e.g. reading PINT to rhyme with hint, flint, etc.). This pattern, known as surface dyslexia (or dysgraphia), has been attributed to the loss of semantic support which is necessary for the correct pronunciation of irregular words. Patients perform normally on non-verbal problem-solving tasks, such as Raven's Matrices, and on tests of perceptual and spatial ability.

NON-FLUENT PROGRESSIVE APHASIA

The status of patients with the non-fluent form of progressive aphasia within the spectrum of FTD is less certain. Changes in behaviour are rare, but after a number of years global cognitive decline occurs. Unlike the other syndromes, a number of non-fluent cases have Alzheimer pathology[17].

Patients present with complaints of speech dysfluency and distortion or word-finding difficulty. Phonological errors are usually obvious in conversation. Comprehension is relatively well preserved, at least in the early stages, although as the disease progresses there are problems with phoneme discrimination, which the patients invariably attribute to poor hearing. In the late stages patients become mute and effectively ''word deaf''. Day-to-day memory is good and patients cope well in everyday life.

Neuropsychological Findings

The pattern of cognitive deficits in progressive non-fluent aphasia is the mirror image to that found in semantic dementia. They perform well on tests of semantic memory, except on those requiring a spoken output. Although conversational speech is severely disrupted, the anomia is mild and the errors are phonological (efelant for elephant). Semantic category fluency is less affected than letter fluency. Word–picture matching, synonym tasks and other semantic tests are usually performed perfectly. They perform poorly on tests of phonological competence (such as repetition of multisyllabic words and rhyming) and syntactic comprehension[16]. In common with the other syndromes, however, performance on visuo-spatial and perceptual function is well preserved.

NEURORADIOLOGICAL FINDINGS IN FTD

CT scans are of limited value in diagnosis: the temporal lobes are poorly seen due to bone artefacts but MRI with coronal images is extremely valuable, especially in cases with semantic dementia who show focal atrophy of the polar region, fusiform and inferolateral gyri with relative sparing of the hippocampal formation. An asymmetric pattern is almost invariable, with the left temporal lobe much more often involved than the right[18]. In non-fluent cases the changes are more subtle, with widening of the left Sylvian fissure. In dementia of frontal type, atrophy of the orbitofrontal cortex can be seen, but ^{99}Tc–HMPAO–SPECT is more valuable: focal hypoperfusion is apparent before clear structural changes are obvious[11,19].

MANAGEMENT

The management of patients and their families requires a specialist multidisciplinary team approach with input from clinical psychology, genetics, psychiatry and neurology. Counselling, especially with regard to genetic implications and prognosis, are essential at an early stage. Although there are, at present, no therapies that will affect the course of the disease, many of the symptoms can be helped. The stereotypical features, disinhibition and overeating, may respond to serotonin reuptake blockers[20]. Neuroleptic drugs may be necessary to control aggressive behaviour.

Alcoholic and Other Toxic Dementias

E. M. Joyce
Imperial College School of Medicine, London, UK

ALCOHOLIC DEMENTIA

The concept of a dementia consequent upon the effects of long-term alcohol abuse developed from clinical observations of a gradual deterioration in personality and intellect in many alcoholics. Recent studies suggest that this is age-related, is milder in degree than the neurodegenerative dementias and can be present in 11–24% of demented patients[1–3]. Alcoholic dementia was originally considered to be distinct from the amnesia of the Wernicke–Korsakoff syndrome, which also occurs in alcoholics but is caused by thiamine malnutrition rather than alcohol neurotoxicity. Horvath[4] prospectively examined 100 chronic alcoholics presenting with a dementia syndrome and concluded that "alcoholic dementia" is not synonymous with the Wernicke–Korsakoff syndrome, and that other non-amnesic organic syndromes exist in alcoholics, characteristic of frontal, parietal or global cortical damage. Cutting[5] performed a retrospective case-note analysis of alcoholic patients with cognitive impairment and found two forms of clinical presentation. One consisted of a rapidly developing illness in younger patients with preserved intellect, akin to the traditional Wernicke–Korsakoff syndrome, whereas the other was more characteristic of dementia, being a gradual and global cognitive deterioration in older patients.

This concept was soon challenged by the results of clinicopathological studies. Torvick *et al*.[6] examined the clinical records of patients who, at autopsy, had diencephalic lesions characteristic of thiamine malnutrition. Of these, 75% were considered to be demented in life rather than amnesic and the majority had no additional neuropathological hallmarks of a neurodegenerative dementia. Torvick *et al.* concluded that the diencephalic lesions of thiamine deficiency can result in the clinical pictures of both "alcoholic dementia" and the Wernicke–Korsakoff syndrome. Victor and Adams[7] then pointed out that 10% of their pathologically-proven cases of the Wernicke–Korsakoff syndrome developed cognitive abnormalities insidiously, rather than acutely[8], and that cognitive impairments other than amnesia, and behavioural abnormalities such as inertia and apathy, can be demonstrated in these patients[9]. Thus, they argued that, depending on the severity of the non-mnemonic deficits or the mode of presentation, cases of the Wernicke–Korsakoff syndrome may be misattributed as cases of alcoholic dementia. The neuropathological studies of Harper and colleagues[10,11,62] are in agreement with this. They found that two-thirds of the alcoholics coming to post mortem in their unit had lesions of thiamine deficiency, yet only one-third of these had received a clinical diagnosis of Wernicke–Korsakoff syndrome in life. In the remainder, the most common diagnosis was dementia.

Thus far, the evidence points to the conclusion that subcortical lesions caused by thiamine malnutrition can be sufficient to explain both amnesia and dementia witnessed in alcoholics. However, Victor and Adams[7] and Torvick *et al*.[6] did not assume that *all* cases of alcoholic dementia are unrecognized cases of the Wernicke–Korsakoff syndrome. Both considered that superadded cerebral lesions may explain the dementia-like presentation of a proportion of patients with the Wernicke–Korsakoff syndrome. Because these additional lesions can be attributed to a variety of pathological processes, including chronic hepatocerebral degeneration, communicating hydrocephalus, Alzheimer's disease and ischaemic infarction, they argued that there is no need to invoke a special process of alcohol neurotoxicity. More recent research supports this contention. Kasahara *et al*.[2] compared young (35–45 years) and old (>60 years) alcoholics and found evidence of dementia only in the older group. Most cases had additional medical diagnoses, including hypertension, liver disease and cardiomyopathy, and no case of dementia could be accounted for by the direct effect of alcohol.

Although dementia in alcoholics is unlikely to be caused solely by alcohol neurotoxicity, there is compelling evidence to suggest that alcohol is neurotoxic. Carefully controlled neuropathological studies have frequently found whole brain atrophy, predominantly involving the white matter, in chronic alcoholics[12–16]. Neuronal death has been found in specific areas of the frontal association cortex[17–19] and neuronal shrinkage in the cingulate and motor cortex[17,20,21]. The contribution of liver failure to this neuropathology has been assessed in several studies and the bulk of evidence suggests that cirrhosis alone does not account for the brain shrinkage witnessed in alcoholics[13,15,22]. However, existing studies of the contribution of thiamine malnutrition to such findings are equivocal with evidence that thiamine deficiency both does and does not cause the cortical damage seen in alcoholics[13,15]. Medial temporal lobe limbic structures, i.e. the hippocampus and the amygdala, have been foci of interest because of their involvement in cognitive function. Reduced volumes have been reported in alcoholics but, again, it is not clear whether it is alcohol *per se* or thiamine deficiency that accounts for this[16,19,23–25].

It can be concluded from these studies that: (a) alcohol itself can cause neuronal damage; (b) liver disease *per se* is not a major factor in the aetiology of the neuropathological changes; and (c) thiamine malnutrition potentiates the neurotoxic effect of alcohol on the brain. Butterworth[26] proposes mechanisms to explain these conclusions. He argues that thiamine deficiency is common in alcoholism because of poor diet and gastrointestinal disorder. Alcohol and its metabolite acetylaldehyde are directly neurotoxic and have toxic effects on thiamine-dependent enzymes in brain and liver. In turn, liver disease disrupts thiamine homeostasis and causes astrocytic damage. The latter results in the loss of neuron–astrocyte trafficking of neuroactive amino acids and thiamine

esters essential to CNS function. Thus, there are several possible routes to the production of brain damage in alcoholics. Further, these appear to be so interlinked that it may be unproductive to try and dissect the separate contribution of alcohol and thiamine deficiency to brain damage. Rather, it appears that a combination of malnutrition and alcohol intake can give rise to a range of cognitive deficits, from mild cognitive impairment to severe dementia, depending on the severity of the contributory abnormal mechanisms described by Butterworth.

Although the evidence points to alcohol being neurotoxic, the relationship between this and cognitive impairment is not clear. A major drawback of neuropathological studies is that such inferences have been either not possible or gleaned by retrospective case note analysis. In contrast, neuroimaging allows the prospective analysis of clinical features in relation to *in vivo* brain structural and functional abnormalities. Well-controlled, prospective studies using both CT and MRI have reliably confirmed the presence of cerebral shrinkage in alcoholics in life, involving both cortical grey and subcortical white matter[27–34] which are more pronounced in older patients[35] and more apparent in the frontal lobe[36,37]. The percentage of alcoholics with evidence of cerebral atrophy on brain scans is far in excess of that noted in neuropathological studies[12]. This discrepancy is probably explained by the finding that brain changes are reversible with continuing abstinence[29,33,34,38–42] indicating that neuroimaging findings do not accurately reflect the permanent neuropathological changes previously described. Some studies have found that the neuroimaging changes worsen in patients who continue to drink[41,43,44]. A recent carefully controlled study, in which alcoholic men and controls were followed over 5 years[45] found that a greater total alcohol consumption was associated with greater decrease in cortical grey matter, particularly in the frontal lobe. Thus, it is possible that prolonged alcohol ingestion leads to irreversible brain damage, which might be mirrored by irreversible cognitive deficits.

There is certainly no doubt that cognitive dysfunction can be witnessed in uncomplicated alcoholics, even though these may not reach the severity required for a diagnosis of dementia. Parsons[46], following decades of his own research, concludes that both male and female sober adult alcoholics have deficits on tests of learning, memory, abstracting, problem-solving, perceptual analysis and synthesis, and speed of information processing, which are equivalent to those found in patients with known brain dysfunction of a mild to moderate nature. Such abnormalities can also be witnessed in adolescent alcoholics[47]. Further attempts to identify factors other than alcoholism to account for these differences have been unsuccessful[46]. It is noticeable, however, that, like neuroimaging studies, these deficits are largely reversible over weeks or years of abstinence[46,48]. This may explain why studies relating cognitive and structural changes in alcoholics found weak and inconsistent correlations, the majority of which were explained mainly by age and premorbid IQ[27–30,50].

Functional imaging studies have been a bit more fruitful in this regard. One study found a reduction in overall cerebral glucose utilization[51] but all other studies found specific regional changes. For example, Samson *et al.*[52] have shown a relative decrease in glucose utilization within the medial frontal cortex of six recently detoxified neurologically intact chronic alcoholics, and Gilman *et al.*[53] have also reported the same finding in 14 alcoholics studied after at least 27 days of abstinence. In the latter study, patients made errors on the category sorting test, a test of frontal lobe function, and this correlated with glucose utilization in the medial frontal cortex. However, in a small-scale follow-up study from the same group, these deficits were partially reversible with abstinence[54] and it is not clear whether they become irreversible with continued drinking.

DISCUSSION

There are several conclusions that can be made from these studies concerning the validity of alcoholic dementia. First, diffuse cognitive impairment in alcoholic patients is common. It is an age-related phenomenon and the cognitive deficits are more mild than in patients with neurodegenerative dementias. Alcohol itself can produce irreversible brain damage, mainly of white matter and the frontal association cortex, but most studies suggest that frank dementia cannot be ascribed entirely to alcohol neurotoxicity. Other causes should therefore be sought, most notably thiamine deficiency. In younger patients, alcohol alone can also produce diffuse cognitive and cerebral abnormalities but these are largely reversible with abstinence. It remains to be determined which factors lead to the permanent alcohol-induced neuropathology seen at post mortem.

OTHER TOXIC DEMENTIAS IN THE ELDERLY

The acute and chronic psychiatric effects of ingestion of drugs of abuse, including those most relevant to the elderly—barbiturates and benzodiazepines—have been extensively reviewed by Lishman[55]. Suffice it to say that there is little evidence to suggest that these produce diffuse cognitive impairment. The neuropsychiatric effects of long-term occupational solvent exposure is also relevant to the elderly. Although there is controversy concerning whether solvents *per se* produce long-lasting effects, most studies find evidence for lasting neuropsychological abnormalities[56–59]. Of particular interest is that these studies also found that a combination of long-term solvent exposure and alcohol abuse is a particular risk factor for the development of dementia. Of final relevance to this age group is the identification of bismuth encephalopathy, which results from the over-ingestion of bismuth-containing compounds commonly taken for gastric irritation and sold without prescription. Following an acute organic reaction characterized by delirium, seizures and neurological abnormalities, persistent sequelae of diffuse cognitive impairment and cerebral atrophy have been documented[60,61].

Reversible Dementias

Michael Philpot and Jerson Pereira
South London and Maudsley NHS Trust, London, UK

The early literature on this subject includes numerous case series, or even single case studies, of "dementia" that seemingly resolved following treatment of the associated physical or psychiatric condition. Undoubtedly, many of the patients were actually suffering from delirium or other organic brain syndromes, an observation that is discussed in more detail by Byrne[1]. Confusion over terminology has complicated research in this area. For example, the concept of "reversible" dementia appears at odds with the European use of the term "dementia", denoting an insidiously progressive disorder[2]. In addition, the relationship between delirium and dementia is a complex one and is dealt with elsewhere in this textbook.

This chapter reviews the classification and prevalence of *potentially* reversible dementias in clinical practice, the issue of response to treatment and the cost–benefit of routine investigation. A detailed presentation of the numerous causes of reversible organic brain syndromes is provided by Lishman[2].

CLASSIFICATION

A useful scheme, which clarifies terminology, has been suggested by Maletta[3] and is shown in Table 53.1. Secondary dementias are those arising from a specific physical disorder. Drug intoxication and metabolic disorders include more acute conditions, often in association with impairment of consciousness, which clearly overlap with delirium but which have traditionally been included in studies of reversible dementia. Dementia due to psychiatric disorders includes those conditions classically referred to as the "pseudodementias"[4] mostly secondary to primary depressive illness.

PREVALENCE

The frequency with which potentially reversible dementias occur in clinical practice is an important factor in determining the rigour with which contributory physical disorders or other causes are pursued. A previous review[5] concluded that approximately 12% of patients presenting to a variety of specialist services with symptoms of dementia had treatable causes. This review was based on case series published during the 1970s and 1980s[6–11]. The prevalence of potentially reversible disorders was 18% in patients under the age of 65 years but only 5% in those over 65. Depression, drug toxicity and normal pressure hydrocephalus accounted for more than half the cases. Identification rates were higher in specialist inpatient units than in outpatient or community-based studies. Importantly, though, these studies largely failed to review patients at a later date in order to determine the true reversibility of their cognitive symptoms.

Table 53.2 shows a selection of surveys of the potentially reversible dementias published during the 1990s[12–18] grouped by specialty. Each was carried out in the setting of an outpatient memory clinic. Rates of identification of physical disorders were generally lower than in the earlier series. It has been suggested that the increasing awareness of the features of dementia and the use of internationally agreed diagnostic criteria has helped to refine clinical diagnosis[19]. This has resulted in a more rigorous exclusion of doubtful (non-dementia) cases at an early stage. Esoteric aetiologies are conspicuous by their absence, despite the comprehensive investigation carried out. This is likely to reflect the more representative nature of the patients studied. However, memory clinics specializing in the assessment of patients under the age of 65 usually still report higher rates of identification of potentially reversible conditions, particularly depression[20,21].

Table 53.1 Classification of potentially reversible dementias

Reversible dementias	Common clinical examples
1. Secondary dementias	
Associated with neurological disorders	
Structural lesions	Normal pressure hydrocephalus, brain tumour, subdural haematoma
Associated with systemic disorders	
Nutritional disorders	Vitamin B_{12} deficiency, folate deficiency
Endocrine disorders	Hypothyroidism, hyperthyroidism, hypoparathyroidism
Collagen/vascular disorders	Systemic lupus erythematosus, cerebral vasculitis
Infectious diseases	Neurosyphilis, chronic meningitis, AIDS
Alcohol related disorders	Primary alcoholic dementia
Miscellaneous	Chronic obstructive airways disease, sleep apnoea syndrome
2. Drug intoxication and metabolic disorders	Intoxication with major and minor tranquillizers, anti-hypertensives
3. Dementia due to psychiatric disorders	Depression, late-onset schizophrenia

After Maletta[3].

Table 53.2 Outcome of investigation of patients presenting with clinical symptoms of dementia

Studies	Brodaty[12] Almeida *et al.*[13]	Ames *et al.*[14] Freter *et al.*[15]	Chui & Zhang[16] Walstra *et al.*[17] Hogh *et al.*[18]
Memory clinic specialty	Geriatric psychiatry	Geriatrics	Neurology
Total patients studied (*n*)	558	405	719
Clinical dementia confirmed [*n* (%)]	368 (100)	270 (100)	451 (100)
Mean age (range) (years)	70 (44–90)	76 (49–92)	66 (19–97)
Potentially reversible dementias

Drug intoxication and metabolic disorders [*n* (%)]:	0	13 (4.8)	0
Alcohol abuse	–	2	–
Drug toxicity	–	11	–
Psychiatric disorders [*n* (%)]:	0	23 (8.5)	7 (1.6)
Depression	–	23	7
Follow-up period (months)	>6	>4	6[†]
'True' reversible dementia [*n* (%)]	0	5 (1.9)	2 (0.4)[†]

[†] Not stated in Hogh *et al.*[18]

RESPONSE TO TREATMENT

The degree to which reversible dementias are, in fact, reversible has long been the subject of debate. Rabins[22] reported some improvement in two-thirds of patients and complete recovery in 40%. This looks optimistic, judging by the results presented in Table 53.2 of between 0% and 2% reversibility.

A number of conditions deserve special mention. Depressive ''pseudodementia'' has traditionally been viewed as a treatable condition, with a distinct clinical history and symptoms that distinguish it from ''true'' dementia[23]. In an attempt to improve the clinical discrimination between depressive pseudodementia and progressive dementia, Yousef *et al.*[24] derived a rating scale from a large number of possible discriminating features. Validating the diagnosis 12–14 months later, the scale allowed correct classification of 98% of true dementia cases and 95% of depression cases. Longer-term follow-up studies tend to support the view that severe cognitive impairment in depression is a harbinger of true dementia in 25–50% of patients[24–26]. Alexopoulos *et al.*[26] found that, after 2–3 years, elderly depressed patients who also fulfilled DSM–III criteria for dementia were nearly five times more likely to develop dementia than those without cognitive impairment at presentation. The issue is further complicated by the high prevalence of depressive symptoms in dementia[27].

Several authors have questioned the usefulness of routine syphilis serology[28–30], while others have defended routine testing on the grounds that even one missed case would be catastrophic for the individual patient[31]. However, the erroneous diagnosis of active syphilis perhaps carries with it equally dire consequences, particularly when false positives may occur as a result of yaws and other non-venereal treponemal infection[32]. Hilton[33] has suggested that treatment should not be based solely on positive serology and that testing for syphilis should be dealt with in the same way as HIV testing and require informed consent where possible.

Normal pressure hydrocephalus is the most common neurological cause of reversible dementia[16–18]. However, the results of shunting operations indicate high rates of post-operative complications, including death, as well as a lack of evidence of effectiveness[34–35]. The best results are obtained in patients under the age of 60 years who present with dementia of less than 6 months' duration[34].

Clearly, the lack of reversibility revealed by the studies listed in Table 53.2 suggests that most of the associated disorders are really *concomitant* with true dementia, rather than of aetiological significance. They may also be secondary to the dementia, e.g. anaemia as a result of malnutrition. Hogh *et al.*[18] reported that 45% of those with dementia were found to have concomitant disorders. Although treatment of depressive symptoms in dementia has been shown to improve some aspects of cognition and everyday function[36,37], there is little evidence to show that the correction of other disorders, such as hypothyroidism or vitamin B_{12} deficiency, has similar benefits[17,38,39].

Table 53.3 Physical investigations for the assessment of an elderly patient presenting with cognitive impairment

Routine investigations (all cases)	Special investigations (atypical cases or clinically indicated)
Full blood count[a,b,c]	Brain CT or MRI[a,b,c]
Erythrocyte sedimentation rate[b]	EEG[a,c]
Renal function[a,b,c]	Chest X-ray[a,b,c]
Liver function[a,b,c]	Electrocardiogram[b,c]
Thyroid function[a,b,c]	Lumbar puncture[a,c]
Calcium[a,b,c]	
Vitamin B_1[c]	
Vitamin B_{12}[a,b,c]	Urine for culture[a,b]
Folate[b,c]	
Glucose[a,b,c]	HIV testing[a]
Syphilis serology[a,c]	Toxicity screen[a]
	Auto-antibody screen[b]

Recommendations for investigations: [a]American Academy of Neurology[40]; [b]Royal College of Psychiatrists[42]; [c]Dutch Consensus statement[44].

INVESTIGATION PROTOCOLS

A number of organizations have published guidelines for the investigation of dementia, largely with the aim of identifying the common reversible dementias[40–44]. Table 53.3 lists investigations suggested in three sets of consensus statements[40,42,44] and shows that there is broad agreement on the appropriate routine blood investigations. Chui and Zhang[16] examined the added value of the investigations recommended by the American Academy of Neurology[40]. After a complete clinical assessment, blood tests and neuroimaging results changed management in only 13% and 15% of cases, respectively. van Crevel *et al.*[44] found that the number of patients requiring investigation to find one case of reversible dementia was approximately 100, and that any financial saving on care costs was insignificant. Lastly, Foster *et al.*[45], in a detailed examination of the cost-effectiveness of routine computed tomography (CT), concluded that patients aged over 65 years should only be scanned if symptom duration was less than 1 year, if symptoms were rapidly progressive or if the presentation was atypical of Alzheimer's disease. Routine scanning was recommended in all patients presenting under the age of 65.

CONCLUSION

Reversible dementias are rare but their identification is important from the individual patient's perspective. The literature encompasses a polarization of views. The evidence-based view would suggest that extensive investigation is unnecessary and that, in any case, treatment of identified disorders is largely ineffective. The more traditional, patient-centred view, perhaps coloured by the early literature and the fear of litigation, would demand the continued use of routine investigations in the hope of excluding treatable aetiologies, however rare. The introduction of care protocols reached by consensus should guide clinicians and ensure that patients have equity of access to appropriate assessment.

Differential Diagnosis of Dementia

Charlotte Busby and Alistair Burns
Withington Hospital, University of Manchester, UK

When approaching the differential diagnosis of dementia, two distinct but related issues are involved. First, the clinician has to consider whether the patient is suffering from a dementia syndrome. Differentiation has to be made from a functional psychiatric disorder, such as depression, which may be manifested as a dementing illness (so-called "pseudodementia" or the dementia syndrome of depression); from an acute organic reaction (acute or subacute confusional state); from the effects of normal ageing[1], from pre-existing handicaps; and from the deleterious effects of drugs. Second, the aetiology of the dementia, in terms of either a potentially reversible or irreversible dementia, has to be uncovered. The process is illustrated in Figure 54.1, although in practice a clinician formulates a diagnosis based on the whole presentation (see also ref. 2). This chapter will not deal with Alzheimer's disease in detail (see ref. 3) but it will be regarded as a prototype against which other disorders can be compared.

There are clinical situations in which the diagnosis of dementia is problematic. These have been well summarized[4] and include: early cases (where the effects of normal ageing need to be considered); patients with a low IQ (where intellectual symptoms may be noticed early); very old patients, especially when residents of nursing homes, without reliable informants; patients with impaired vision and hearing; patients who are mentally handicapped; patients with prominent psychiatric problems, such as paranoia, dysthymia or personality problems; and those with severe physical illness or an intercurrent delirium.

When evaluating a patient with possible dementia, the following should be performed[5–7]:

- Detailed family and personal history and history of the current illness from a reliable informant.
- Mental State Examination of the patient, with particular reference to the cognitive state (amnesia, apraxia, aphasia and agnosia); more detailed neuropsychological assessment should be considered if particular deficits are suspected).
- Physical examination, with particular emphasis on the central nervous system.
- Investigations including haematological and biochemical blood tests, serum B_{12} and folate, thyroid function tests, chest X-ray and ECG.

Some form of assessment of cerebral function/structure is desirable, the nature of the investigation being dependent on local facilities. An electroencephalogram (EEG) should be performed and is widely available. Ideally, a computed tomography (CT) scan should also be carried out, but this is not always practicable. If so, it is reasonable to limit this examination to cases in whom there is reason to suspect an intracranial lesion, i.e. clinical suspicion of such a lesion, evidence of cerebral infarction, focal neurological signs, seizure activity, a head injury thought to be contributory to the clinical picture, or a suspicion of normal pressure hydrocephalus. The main conditions in the differential diagnosis of dementia and possible causes of the dementia syndrome are discussed below.

ACUTE CONFUSIONAL STATE (DELIRIUM)

This is the most important differential diagnosis to be considered, as there is almost always a physical disorder underlying its presence. Onset is acute, disturbances often severe and the patient is usually brought to the attention of the services by worried friends, relatives or neighbours. There is a global disturbance of cognition, with marked fluctuation over the course of the day, often worse at night[8].

During affected periods, there is almost always some disorientation. Among the disturbances are disorders of perception (characterized by an inability to interpret events and to discriminate them from images and dreams), disorders of thinking (disorganized, fragmented and with disjointed thoughts and decreased ability to plan or solve problems) and disorders of memory (registration, retention and retrieval are all affected). Clouding of consciousness is the cardinal feature of delirium and has been defined in terms of a disorder of attention (decreased or increased alertness, selectiveness and directiveness) and wakefulness (diminished night sleep[9]). Psychomotor behaviour is usually disturbed, with overactivity, underactivity or a mixture of the two. The diagnosis of acute confusion is made on a characteristic history of a sudden onset of disturbance and the findings outlined above on examination of the patient. Often the physical precipitant is not obvious initially (and in a proportion of cases is never discovered). An underlying dementia may be present and is suggested by the history.

PSEUDODEMENTIA

In this condition, symptoms of disorientation and memory loss occur in a non-organic psychosis and mimic dementia. The original description of cases included patients with a number of functional psychiatric disorders[10], but in practice depression is by far the commonest cause. In contrast to dementia, the clinical course of the condition is relatively short and has a defined date of onset. There is often a previous history and/or a

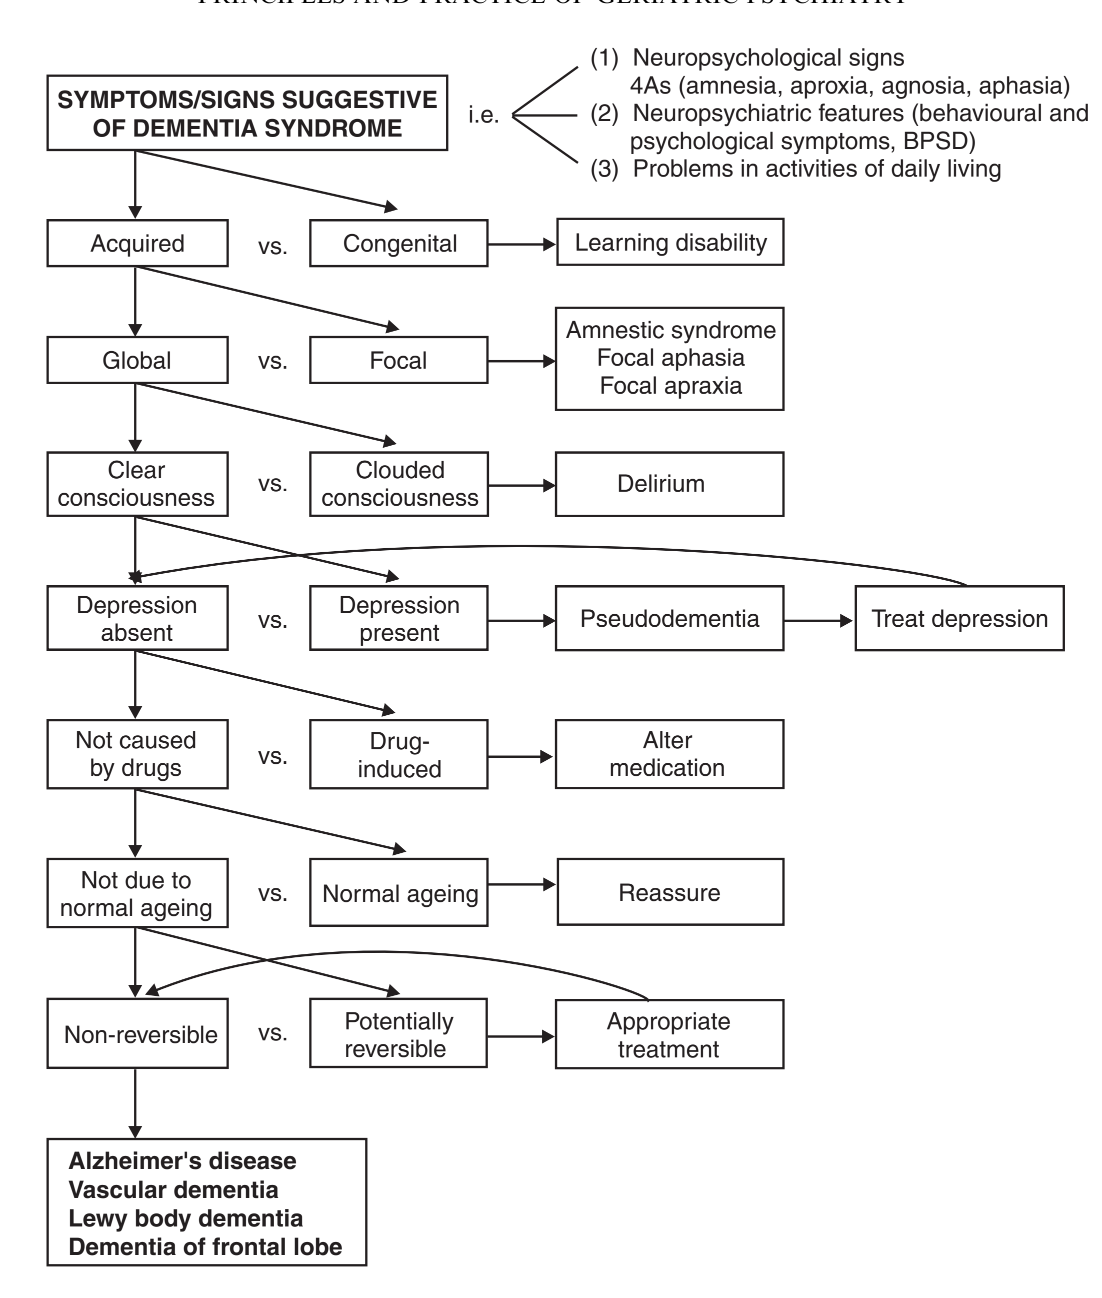

Figure 54.1 Diagnostic algorithm for dementia

family history of affective disorder. Patients tend to answer questions with "don't know" responses, there is a variability in their ability to perform tasks of similar difficulty, they communicate a sense of distress and complain of their cognitive deficits[11]. Structural brain changes have been described in this condition[12]. Pseudodementia is currently a term in disrepute and the alternative (dementia syndrome of depression) is considered to be more accurate. The diagnosis of pseudodementia is made on clinical grounds and should always be considered in a demented patient. Validation of the diagnosis is by successful treatment and return to normal of the cognitive deficit[13,14]. Some clinicians would argue that a trial of antidepressants should be given in all cases of dementia.

VASCULAR DEMENTIA

There are two main types of vascular dementia, one involving subcortical structures affecting small arteries, leading to the clinical picture of subcortical dementia (see below for cardinal features), and one involving medium-sized arteries (anterior, middle and posterior cerebral arteries), leading to a cortical dementia. The clinical features of vascular cortical dementia have been defined in the Hachinski score[15]. Physical examination will generally reveal neurological signs, such as disturbances of gait rigidity, spasticity and reflex abnormalities, and CT often reveals cerebral infarction. Diagnostic criteria have been described[16,17].

INTRACRANIAL LESIONS

Any form of intracranial mass lesion may masquerade as dementia. Cerebral tumours (primary or secondary), brain abscess or intracranial bleeds may all give rise to a dementia syndrome. Diagnosis is made through suspicion of the primary lesion and visualization on CT scan.

SUBCORTICAL DEMENTIA

This is a generic term for a particular syndrome of dementia, which has particular clinical features separating it from a cortical dementia. These include mental slowness, inertia, apathy and loss of initiative, occurring along with cognitive disturbances. The diseases associated with subcortical dementias include Parkinson's disease, Huntington's disease, progressive supranuclear palsy, Wilson's disease, spinocerebellar degeneration, hydrocephalus and the toxic/metabolic encephalopathies. The structures affected are subcortical—the basal ganglia, thalamus and the brain stem.

In Parkinson's disease, there is mental slowing, diminished problem solving, poor memory and a deterioration in abstraction, concept formation and word generation. Depression is common, as in all subcortical dementias. Cortical features (such as aphasia, apraxia and agnosia) are absent, although some authors claim there is a cortical dementia present, probably due to coexisting Alzheimer's disease. The diagnosis of Parkinson's disease is essentially a clinical one and physical manifestations of the disease will generally be present when the dementia is apparent.

Huntington's disease is characterized by choreiform movements and associated with autosomal dominant transmission. Personality changes, irritability and apathy are the first changes and predate the chorea. The dementia appears soon after the movement disorder becomes apparent, characterized by memory disturbance (impaired recall of both recent and remote memories), slowing, failure to initiate cognitions (especially those required in planning) and impaired concentration and judgement[26]. Although dementia without chorea has been described, it is very rare and the diagnosis of Huntington's disease is usually suspected prior to the onset of dementia[18].

Pseudobulbar palsy, rigidity (more pronounced in the neck and trunk) and paralysis of vertical gaze (downward gaze lost first, followed by failure of upward gaze) are hallmarks of progressive supranuclear palsy, and the associated dementia is classically subcortical (indeed, the original description of subcortical dementia was based on the dementia of progressive supranuclear palsy). Speech is disrupted (e.g. dysarthria and hypophonia) but aphasia is absent. The clinical features are such that the diagnosis will often be suspected and, although it may be confused with Parkinson's disease, the characteristic tremor of the latter is absent.

Other conditions resulting in subcortical dementias occur rarely and are of limited relevance to old age psychiatry. The amyotrophic lateral sclerosis–Parkinson–dementia complex of Guam is rare outside the Chonorro population of the Western Pacific, the dementia being profound and characterized by features of decreased memory, apathy and slowness; cerebellar degenerations are associated features of subcortical dementia but the cerebellar dysfunction is usually the prominent feature; Wilson's disease and Friedreich's ataxia are associated with dementia, but are confined to children and young adults.

NORMAL PRESSURE HYDROCEPHALUS

A potentially treatable cause for a dementia syndrome is hydrocephalus, the most widely cited being normal pressure hydrocephalus. The classical clinical triad consists of gait disturbance (ranging from mild clumsiness to akinesis), incontinence (almost always urinary incontinence, occurring late in the illness) and dementia (impaired memory, disorientation and mental slowing). The diagnosis is made by radiological examination (CT scan shows marked enlargement of the ventricles with relatively normal cortical sulci, and isotope cisternography shows obstruction to the flow over the cortex). A ventricular shunt to divert cerebrospinal fluid is the appropriate treatment but not all cases improve, even when the classical clinical picture is present.

PICK'S DISEASE

Personality changes and mood disorders (ranging from depression to elation) occur first, with coarsening of affect and antisocial behaviour. Impaired judgement occurs, with loss of insight. Aphasia and circumlocution occur early. Memory is relatively unimpaired until the later stages of the disease, as is praxic function. The Kluver–Bucy syndrome has been described early in the illness, but this also appears in Alzheimer's disease[19]. Extrapyramidal signs appear late in the illness but the clinical picture is unlikely to be confused with Parkinson's disease. Seizures are said to be less common than in Alzheimer's disease and CT scan shows frontal and temporal lobe atrophy, rather than the generalized shrinkage seen in Alzheimer's disease. The diagnosis is made on the basis of the characteristic onset of personality changes before the onset of dementia.

DEMENTIA OF THE FRONTAL LOBE TYPE

Recently, descriptions have emerged of a form of dementia that appears to affect the frontal lobes and is defined in terms of clinical presentation (personality change, speech impairment and relative preservation of visuospatial functions), neuropsychological function (frontal lobe syndrome) and blood flow studies (diminished frontal lobe blood flow on single-photon emission tomography)[20–22]. There is frontal and temporal lobe atrophy and, while the condition resembles Pick's disease, the characteristic neuronal inclusion bodies are absent. Diagnosis is made on clinical grounds but confirmation usually has to await autopsy.

DEMENTIA OF LEWY BODY TYPE

This has been described with increasing frequency and is considered to be amongst the commonest forms of primary dementia[23]. The relationship of this syndrome to Parkinson's disease is uncertain, but the clinical picture of parkinsonian features, hallucinosis and episodes of confusion should raise the diagnostic possibility.

TOXIC-METABOLIC ABNORMALITIES

Generally, these are readily identifiable by the primary cause for the syndrome (such as anoxia, renal or hepatic failure) and the symptomatology produced is more often identifiable as an encephalopathy rather than a dementia syndrome. There are a

few conditions of relevance in old age psychiatry, which will be outlined briefly. Systemic carcinomas may produce effects in the brain by several mechanisms through metabolic disturbances (such as excess secretion of adrenocorticotrophic hormone or antidiuretic hormone), through structural change (cerebral secondaries or infections) or through remote effect (limbic encephalitis). This last condition is common in men, particularly with oat cell carcinomas of the lung, and has a course of up to 24 months. Affective changes dominate the picture, with amnesia the primary (and occasionally the sole) abnormality. Diagnosis of the condition is through attention to the physical condition of the individual. Vitamin deficiencies (notably B_{12} and folate) cause mental impairment, but routine testing for their levels makes the diagnosis relatively easy. The same holds true for thyroid dysfunction and hypercalcaemia. Chronic excessive alcohol intake can result in a dementia[24].

CREUTZFELDT–JAKOB DISEASE

Early features include fatigue and listlessness, elevated mood and impaired memory and concentration. Motor abnormalities occur with spasticity, ataxia and tremor. Myoclonic jerks and seizures may occur. The EEG is very abnormal, with characteristic triphasic waves superimposed on some suppression of the background rhythms. The course of the illness is very rapid and most affected individuals are dead within 2 years[25].

SUMMARY

The differential diagnosis of dementia is a two-stage process: first, the differentiation of dementia from other causes of cognitive impairment; and second, if it is found to be a form of dementia, the elucidation of the aetiology. Alzheimer's disease is the commonest form of dementia, cerebrovascular disease is probably the second commonest cause and Lewy body dementia is becoming increasingly recognized. The differential diagnosis of dementia is an excellent example of how simple logical clinical skills can be applied without the need for expensive investigations, which should be reserved for situations where there is clinical doubt about the diagnosis.

Distinguishing Depression from Dementia

William E. Fox and David C. Steffens

Duke University Medical Center, Durham, NC, USA

Recent research continues to confirm the complex relationship between depression and dementia. The ability to distinguish depression from dementia is complicated by the overlap of many of their clinical manifestations. Differentiating the two illnesses is further complicated in that depression and dementia are often concurrent illnesses in the geriatric population. Depression has also become recognized as a possible prodrome, or even risk factor, for degenerative dementias. Finally, cerebrovascular disease, one of the long-established etiologies of dementia, is becoming increasingly recognized as a possible etiology of geriatric depression.

Dementia and depression are two of the most common diagnoses that clinicians encounter in geriatric psychiatry. The prevalence of dementia has been estimated to be approximately 1% at age 60, doubling every 5 years to reach 30% to 50% by age 85[1,2]. Major depression afflicts 1–2% of community-dwelling elderly, with significantly higher rates observed in hospitalized elderly and those residing in nursing homes[3]. The prevalence for minor depression or subsyndromal depression is even higher, with rates reported to be 13–27%[3].

Given the complex relationship between depression and dementia, combined with high prevalence rates, clinicians need to be familiar with the literature that addresses these issues. This chapter will begin with a review of the basic diagnostic criteria of dementia and depression. It will then explore the key points in clinically distinguishing the diagnoses. Next, it will examine the issue of concurrent depression and dementia, as well as the concept of pseudodementia of depression. It will conclude with a discussion regarding the latest research on the possibility of depression as a herald or prodrome of degenerative dementias, and the newly emerging concept of vascular depression.

CLINICAL PRESENTATIONS OF DEMENTIA AND GERIATRIC DEPRESSION

The DSM-IV diagnostic criteria for dementia include the development of multiple cognitive deficits manifested by memory impairment, and one or more of the following: aphasia, apraxia, agnosia or disturbance in executive functioning[4]. In addition to these core cognitive symptoms, numerous psychiatric symptoms are also common. In Alzheimer's disease (AD), the most common of the dementing disorders[5], significant psychiatric symptoms often occur, including personality changes, irritability, anxiety, delusions, hallucinations and depressive symptoms[5–8]. The depressive symptoms that are common in dementia include sleep disturbance, anorexia, irritability, social withdrawal, anergy and apathy[6,7].

The diagnostic criteria for major depressive disorder, as described in the DSM-IV, include depressed mood, diminished interest, weight loss, sleep disturbance, psychomotor agitation or retardation, loss of energy, feelings of worthlessness or guilt, and diminished ability to concentrate[4]. While not all studies agree, most authors report that in the elderly, compared to younger depressive counterparts, depressed mood and feelings of guilt are not as common but somatic and cognitive symptoms are more common[3,9]. The cognitive symptoms may become so severe as to lead to the development of what has been termed "pseudo-dementia".

With such significant overlap of the symptoms of dementia and depression in the elderly, the clinical or "bedside" differentiation can be quite challenging. Reynolds *et al.*[10] found that patients with pseudodementia of depression showed greater early morning awakening, higher anxiety and more severe impairment of libido. Patients with dementia showed more disorientation to time and greater difficulty with dressing and navigating through familiar surroundings.

The American Association for Geriatric Psychiatry, the Alzheimer's Association and the American Geriatric Society presented a consensus statement that included tips for differentiating dementia from depression[5]. The panel reported that patients with AD, in comparison with depressed patients, tend to minimize cognitive deficits, demonstrate impaired memory and executive function, have "indirect" symptoms of depression, such as agitation and insomnia, and demonstrate other cognitive deficits, such as aphasia and apraxia. The panel further reported that those patients with cognitive disturbance, in the context of depression, in comparison with demented patients, tended to exaggerate cognitive deficits, show impaired motivation and classic mood symptoms and have intact language and motor skills.

Abram and Alexopoulos[11] described the similarities between the clinical appearances of dementia and depression, including shared neurovegetative signs, such as weight loss, insomnia, decreased libido and fatigue. However, they also emphasized that some distinctions can be made clinically. Specifically, the authors asserted that weight loss, fatiguability and insomnia usually reflect acute changes in depression, but will be more chronic in dementia. Mood-incongruent delusions may be found in psychotic depression as well as dementia, but mood-congruent delusions are more characteristic of depression. They also reported that the agitation of dementia often manifests as "pacing", while "hand-wringing" is more characteristic of depression.

Other features of the patient's presentation, as well as personal and family history, can be helpful in distinguishing depression from dementia. Geldmacher and Whitehouse[2] suggested that, in patients with dementia, more often a relative will report decreased

memory in the patient. In contrast, in patients with depression, if cognitive symptoms are reported, it is usually by the patient. They also stated that the duration of the presentation could be helpful in clarifying the diagnosis. Depression is typically of shorter duration than dementia and usually with a more well-defined onset. The authors also recommend a review of personal or family history for depression, and a review of family history for dementia.

SCREENING INSTRUMENTS

The use of various "bedside" screening instruments has been proposed as a way to clarify the diagnoses of dementia and depression. Common instruments used in the diagnosis of depression include the Hamilton Rating Scale for Depression (HAM-D), the Beck Depression Inventory (BDI), and the Montgomery–Asberg Depression Rating Scale (MADRS). In general, many authors have found that general depression screening instruments are less helpful in the diagnosis of depression in the elderly than in the general adult population. Reasons for this age disparity include decreased specificity, due to overlap of many depression symptoms with other common geriatric presentations, including dementia and general medical illnesses. It is also believed that the sensitivity is decreased, as not all of the classic symptoms of depression are as common in the geriatric population as in the general adult population.

A number of depression screening tools specifically designed to be used in geriatric or demented patients have been developed. Among the more commonly used instruments are the Geriatric Depression Scale (GDS), Alzheimer's Disease Assessment Scale (ADAS) and the Cornell Scale for Depression in Dementia (CS). The ADAS relies on observation of the patients and thus avoids many of the difficulties inherent in interviewing a cognitively impaired individual[11]. The CS combines interviews with the patient and caregivers, focusing on behavior during the week preceding the interview, thus taking advantage of available collateral information that many other scales ignore[11,12].

The most commonly used dementia screening tool is the Mini-Mental State Examination (MMSE). The MMSE was developed by Folstein *et al*. in 1975[13]. Since that time, it has become the most widely used examination for rapidly assessing the cognitive status of the elderly[14]. This short test covers a broad range of cognitive domains, including orientation, registration, attention and recall, calculation, language, and constructional ability[15]. Age- and education-specific reference values have been developed to help guide the clinician in the use of the MMSE in various populations[14].

Other tests that have been developed to screen for cognitive impairment in the elderly include the Blessed Dementia Rating Scale and the Short Portable Mental Status Questionnaire (SPMSQ). A quick and simple-to-administer test, the clock-drawing test, has been shown in numerous studies to be a good screening test for dementia[16]. Numerous methods have been developed to score the clock-drawing test, ranging from complex 20-point scales to more simple ordinal scales.

Watson *et al*.[17], developed a scoring system that is based on a seven-point scale. With this method, the patient is instructed to draw numbers within a pre-drawn circle to make the face of a clock. After completion, the clock face is divided into quadrants and the number of digits in each quadrant is counted. An error score of one is assigned for each of the first three quadrants containing any erroneous number of digits and an error score of four is assigned for the fourth quadrant if it contains an erroneous number of digits. A score of 4 or greater has been shown to have a sensitivity of 87% and a specificity of 82% in screening for dementia[16].

Kafonek *et al*.[18] conducted a study to determine the sensitivity and specificity of the MMSE in detecting dementia and the Geriatric Depression Scale (GDS) for detecting depression in an academic center-affiliated nursing home population. They found that, in screening for dementia, the sensitivity of the MMSE was 81% and the specificity was 83% when using a cut-off score of 24/30. The GDS was found to be less sensitive and less specific in screening for depression, with a sensitivity of 47% and a specificity of 75%. Thus, while such screening tools can provide useful additional information, they should be taken into consideration as part of the overall clinical picture and not used as the sole basis for making or excluding a diagnosis.

NEUROPSYCHOLOGICAL ASSESSMENT

Formal neuropsychological testing is often employed to help diagnose dementia and depression in the geriatric population. Neuropsychologists are able to administer a full battery of tests that have at least three distinct functions in the assessment of geriatric patients[19]. The first goal of neuropsychological testing is to aid with differential diagnoses between normal aging, psychiatric disorders and neurodegenerative/dementing disorders. A second common use of formal testing is to establish a baseline from which changes can be tracked over time. This can help in determining the response to treatment for depression or dementia, as well as to systematically follow the progression of dementing disorders. The final common use of neuropsychological testing is to delineate the strengths and weaknesses of a particular patient, to help make clinical recommendations for treatment, daily activities and planning for the future.

In an exhaustive review of the neuropsychological testing literature dealing with the differential diagnosis of major progressive dementias and depression, Rosenstein[20] summarized the major test variables that neuropsychologists have found helpful in distinguishing depression from various dementing disorders. In general, she reports that depressed patients tend to demonstrate normal to slightly reduced attention, memory, visuospatial functions, language, executive function, reasoning and sensory-motor function, with a negative or empty response style and inconsistent performances (even within the same domain). In contrast, patients with AD tend to demonstrate more significant impairment in memory, verbal fluency and executive function (in particular, poor awareness of deficits), with a higher prevalence of false-positive responses and intrusions.

Obviously, the milder the dementia at the time of testing, the milder will be the above-mentioned deficits. However, even mild deficits will be more accurately detected on formal neuropsychological testing than with the usual clinical assessment, or with screening tests such as the MMSE. This increased sensitivity is one of the strengths of formal neuropsychological testing. As part of a prospective epidemiological study of dementia, Jacobs *et al*.[21] administered a comprehensive neuropsychological test battery to a group of initially non-demented older adults, in order to examine the association between baseline scores and subsequent development of dementia. The results of the study indicate that, even in the preclinical phase of AD, deficits can be found in areas of word-finding ability, abstract reasoning and memory.

MacKnight *et al*.[22], in their paper examining the factors associated with inconsistent diagnosis of dementia between physicians and neuropsychologists, concluded that the two disciplines have complementary strengths. The neuropsychologist has superior skills in identifying early cognitive loss, while the physician's expertise arises from a greater ability to assess the impact of the impairment on the patient's ability to function. Thus, if available to the clinician, formal neuropsychological testing can provide very helpful and complementary information.

This is particularly true in those cases where diagnostic uncertainty is high.

LABORATORY EVALUATION

For many years attempts have been made to find a reliable biological marker for depression that could be used to develop a sensitive and specific laboratory test. Early on, investigators examined the use of the dexamethasone suppression test (DST), a neuroendocrine measure of the functioning of the hypothalamic–pituitary–adrenal axis, to distinguish depression from dementia. Although the test appeared to have some discriminatory ability in some of the very early studies[23,24], subsequent research failed to demonstrate its usefulness[25–29]. Presently, the DST is not a routine part of a depression or dementia work-up.

Laboratory studies that should be a routine part of the assessment of dementia include a complete blood count (CBC), urinalysis, serum chemistry panel, liver function tests, thyroid function, serum vitamin B_{12} and folate levels, and syphilis serology[8,30]. A number of these tests are also useful in the evaluation of depression. The most commonly cited are a CBC, serum electrolytes, serum vitamin B_{12} level, serum folate level, and thyroid function. While these laboratory studies do not necessarily help to distinguish depression from dementia, they can help to evaluate a number of possible common etiologies and contributing factors. Should any of these tests have positive results, steps should be taken to correct the abnormality and the patient should then be reassessed for depression or dementia.

Genetic testing is beginning to receive much attention as a possible aid in diagnosing various dementing disorders. Early-onset AD comprises both sporadic cases and those that are now known to represent a collection of single-gene disorders. Specific mutations in three genes have been associated with the early-onset, familial-pattern AD. The identified genes are the amyloid precursor protein (APP) gene on chromosome 21, presenilin-1 (*PS1*) gene on chromosome 14, and presenilin-2 (*PS2*) gene on chromosome 1[31]. In cases where early-onset dementia is suspected, genetic testing is indicated to help confirm the diagnosis and to provide additional information to be used in counseling the patient and family members.

In the more common late-onset form of AD, one gene, apolipoprotein E (APOE), located on chromosome 19, has been associated as a risk factor. This gene has three common isoforms, $\epsilon 2$, $\epsilon 3$ and $\epsilon 4$. Research has shown that the isoform $\epsilon 4$ is associated with the development of AD in a dose-dependent manner, and that the isoform $\epsilon 2$ may be protective for AD in a dose-dependent manner[31–35]. Thus, the more copies of the $\epsilon 4$ allele one carries in one's genotype, the higher the risk for developing AD. One complicating factor in using this genetic test in the differential diagnosis of dementia and depression is that the $\epsilon 4$ allele has also been associated with the development of late-onset major depression in a study by Krishman *et al.*[33] While genetic testing for APOE isoforms can be another helpful piece in distinguishing dementia and depression, it is far from conclusive and is currently not a routine part of a work-up for depressed, cognitively-impaired patients.

ELECTROENCEPHALOGRAPHY EVALUATION

A great deal of research has been conducted examining the ability of electroencephalography (EEG) studies to aid in the diagnoses of depression and dementia. In a literature review of EEG of the elderly, Klass and Brenner[36] reported several reasons why an EEG may be helpful in the evaluation of dementia. First, it may confirm that an abnormality of cerebral function exists. Second, it may indicate that a focal process is present, rather than a diffuse process. Third, it may find that a previously unidentified seizure disorder is present. Finally, certain dementing processes, such as Creutzfeldt–Jakob disease, have pathognomonic EEG change and thus the EEG can be diagnostic in those cases. The authors concluded that, in depression, the awake EEG is usually normal and when abnormalities are found they most often are mild.

As abnormalities of sleep are part of the core symptoms of depression, sleep studies using EEG have been studied extensively for many years in an attempt to find objective variables that could aid in the diagnosis of depression. Variables that have consistently been found in depression include increased rapid eye movement (REM) activity, increased sleep latency, decreased REM latency, increased REM density and high rates of sleep onset REM as compared to normal control subjects[37,38]. Dykierek *et al.*[38] studied the REM sleep parameters that could be useful in differentiating AD from normal aging and depression in the geriatric population. They found that they were able to correctly classify 86% of the patients studied using REM density and REM latency measures. In their study, depressed patients tended to have increased REM density and decreased REM latency, while demented patients tended to have decreased REM density and normal to increased REM latency. While the use of EEG and sleep studies are not a standard part of a dementia and depression work-up, in selected cases they may provide additional information that could be helpful to the clinician.

NEUROIMAGING

Recent years have seen significant advances in the development of technology for imaging the central nervous system. Although the value of neuroimaging in the work-up of dementia and geriatric depression is controversial, many authors present strong arguments for its diagnostic utility. The rationale for the use of magnetic resonance imaging/computed tomography (MRI/CT) scans in the work-up of dementia includes the following: (a) neuroimaging contributes to increased diagnostic accuracy and may detect occult lesions not evident on clinical examination; (b) most physicians' clinical skills in diagnosing AD are not sufficient to abandon imaging; (c) CT or MRI may identify potentially treatable causes of dementia missed by clinical evaluation; (d) imaging protects against possible malpractice suits[39]. The arguments against the routine use of neuroimaging include: (a) lack of cost-effectiveness and low yield (prevalence of $< 5\%$ for clinically significant findings); (b) lack of influence on eventual outcome; (c) imaging may result in unwanted procedures (e.g. surgery) or cause distress to patients; (d) benign small vessel changes on MRI often result in overdiagnosis of vascular dementia (false positives)[40].

Historically, the use of neuroimaging in the work-up of depression has not been as strongly recommended as it has in the work-up of dementia. However, recent research of the possibility of vascular and degenerative etiologies of geriatric depression has raised the issue of whether neuroimaging should be part of the work-up of geriatric depression[41]. As will be discussed later in this chapter, geriatric depression is becoming increasingly recognized as a heterogeneous illness with multiple possible etiologies, including cerebrovascular disease and neurodegenerative disease, as well as the genetic and psychosocial etiologies recognized in the general adult population. As these possible etiologies become better established, the use of neuroimaging may become more helpful in the classification of geriatric depression, thus impacting treatment and prognosis.

Recent research on the diagnosis of AD using MRI estimated measurements of the temporal lobes has demonstrated impressive sensitivity and specificity. O'Brien *et al.*[42], in a study to determine the utility of temporal lobe MRI in distinguishing AD from

depression, normal aging and other causes of cognitive impairment, found that temporal lobe atrophy provided "good separation" between those patients with AD and those with other causes of cognitive impairment. In particular, anterior hippocampal atrophy was associated with a sensitivity of 83% for detection of AD, and a specificity of 80% for controls, 87% for depressed subjects and 89% for others. Jack *et al.*[43] found that measurements of hippocampal atrophy provided a sensitive marker for AD, even in the early stages. However, recent studies linking smaller hippocampal volume with depression may limit the utility of this measure in distinguishing depression from dementia[44,45].

The use of functional neuroimaging technology, such as positron-emission tomography (PET) scans and single photon emission tomography (SPECT) scans in the evaluation of dementia and depression is increasingly becoming a subject of research. Although some interesting findings are beginning to emerge[46–48], functional neuroimaging remains primarily a research tool, with limited application to clinical practice. As the technology becomes less expensive and the research shows more consistent and diagnostically useful findings, functional imaging studies may prove to be very powerful tools.

Overall, the use of any form of neuroimaging as a routine part of the work-up of dementia and geriatric depression remains controversial. The utility of functional neuroimaging is uncertain and its use is limited mainly to research. The utility of structural neuroimaging, such as CT or MRI, is becoming more accepted as part of a dementia work-up, but is just beginning to be considered a part of the work-up for geriatric depression. In distinguishing dementia from depression, these studies can provide another useful piece of information to the clinician. However, as with all diagnostic tests, they are not without expense and potential risks/harms, and should be utilized only when the remainder of the clinical evaluation warrants it.

CONCURRENT DEPRESSION AND DEMENTIA

To this point, depression and dementia have been discussed as though they were mutually exclusive diagnoses. However, they commonly coexist in the geriatric population. This concurrence further complicates the task of making a clear diagnosis in the patient who presents with a combination of mood symptoms and cognitive symptoms. Clinical studies report a wide range of prevalence rates for depression in dementia patients. This variance appears to depend on the criteria used and the population studied. In patients with AD, reported rates for depressive disorders have ranged from 0% to 86%, with most studies showing 30–40%[12,49]. The reported rates of depressive symptoms that do not reach diagnostic criteria for a mood disorder are even higher. Many of the less common dementing disorders, such as Parkinson's disease, Huntington's disease and frontotemporal dementia, have rates of depression that exceed those found in AD[50,51].

In light of the significant co-morbidity of depression and the dementing disorders, a number of authors[12,49] are now arguing that the clinical approach to evaluating the elderly patient with mood symptoms and cognitive symptoms should move from the traditional either/or approach to an and/or approach. The impact of not recognizing depression in the context of dementia is significant. Concurrent depression has been reported to increase the disability of patients by lowering the ability to perform instrumental activities of daily living (IADLs) in the mildly cognitive impaired, and lowering the ability to perform activities of daily living (ADLs) in the more severely cognitively impaired[49]. Concurrent depression has even been associated with a greater than 59% mortality rate during the first year in elderly patients admitted to nursing homes[49]. Thus, the recognition and treatment of depression in the context of dementia can have a profound effect on morbidity and mortality in elderly patients.

"PSEUDODEMENTIA" AND DEPRESSION AS A PRODROME TO DEMENTIA

A great deal has been written about depression with cognitive impairment, generally referred to as "pseudodementia". This has been classically listed as one of the most common causes of reversible dementia. The most commonly described clinical scenario would be of an elderly patient undergoing an evaluation for cognitive impairment and being found to meet diagnostic criteria for depression. With appropriate treatment and resolution of the depression, a significant proportion of such patients would no longer have identifiable cognitive impairment. Increasing evidence, however, has convincingly shown that depression with an initially reversible dementia syndrome will frequently be followed by the development of an irreversible dementia[52,53].

Recent studies have also shown that depressive symptoms in the geriatric population, even without evidence of "pseudodementia", may be a prodrome of degenerative dementias. In a large epidemiological study, Berger *et al.*[54], found a significantly higher number of depressive symptoms in individuals who later developed AD than in those individuals who did not go on to develop AD. Reding *et al.*[55] found that, in a sample of patients evaluated in a dementia clinic, 57% of the depressed, non-demented patients develop frank dementia at a 3 year follow-up. The relationship between preclinical depression and the development of dementia is complicated by the difficulty in discerning whether the depression is truly part of a prodrome phase of dementia or whether it is a risk factor for later development of dementia[35]. In either case, the former concept of pseudodementia, separate and apart from true dementia, is not as clear as it once seemed.

VASCULAR DEPRESSION

Recent research has indicated yet another factor that further complicates the relationship between dementia and geriatric depression. It has long been recognized that depression is a common complication of strokes. It is now beginning to be recognized that depression and mood symptoms can be secondary to "silent strokes" or the accumulation of microvascular lesions in the CNS[41,56–58]. Numerous studies are now reporting that significant proportions of elderly patients with depression have evidence of cerebrovascular disease found on MRI and CT studies[56,57]. In particular, lesions in the basal ganglia, periventricular white matter and deep cortical white matter have been associated with depressive symptoms and depression in the elderly[59,60].

This has led to the development of the "vascular depression" hypothesis. Like the dementia in vascular dementia, the depression in vascular depression is thought to arise from vascular insults to the central nervous system. Instead of affecting the systems involved in cognitive processes, the injuries are thought to affect the systems involved in the maintenance of a normal affective state. Thus, it is possible that cerebral vascular disease can not only result in classic stroke symptoms but can also lead to the development of dementia and/or depression.

CONCLUSION

Distinguishing depression from dementia is a difficult clinical task. The cornerstone of making an accurate diagnosis remains the

clinical information gathered "at the bedside" from the patient and his/her family. Various screening instruments and routine laboratory studies can contribute useful additional information to the clinician. More advanced studies, such as formal neuropsychological testing, EEG, neuroimaging and genetic testing, can be helpful in selected patients. In every case, the clinician must keep in mind the high concurrence rate of dementia and depression, the increasing evidence that geriatric depression may be a prodrome of dementia, as well as the research that points to shared etiologies of dementia and geriatric depression, and thus avoid taking a strict either/or approach.

Benign Senescent Forgetfulness, Age-associated Memory Impairment, and Age-related Cognitive Decline

Kathleen A. Welsh-Bohmer and David J. Madden
Duke University Medical Center, Durham, NC, USA

Changes in cognitive functioning are prevalent in aging. These changes are perhaps best considered as falling along a continuum, with normal aging at one end of the scale and brain diseases producing bona fide dementias at the other end. It is not clear that the continuum of cognitive changes in aging and disease is entirely linear. There may be periods of plateaux in cognitive declines or even improvements in cognition as a function of adaptive brain changes. The relationship of cognitive change in normal aging and brain disease, such as Alzheimer's disease (AD) is an area of active investigation, benefiting from the advances in behavioral methods and imaging technologies[1,2].

Normal aging is now recognized as a complex mosaic of cognitive changes in which there is decline in some areas and a substantial degree of either stability or improvement in others[3]. It has been frequently observed, for example, that *fluid* abilities, those relying primarily on the efficiency of current processing (e.g. measures of spatial and reasoning abilities), exhibit pronounced and approximately linear age-related decline, whereas *crystallized* abilities, those relying more on accumulated knowledge and expertise (e.g. vocabulary measures) exhibit greater stability as a function of age. A prominent feature of normal age-related cognitive change is a decline in the speed of information processing, a decline that is more critical to the functioning of fluid abilities than to the functioning of crystallized abilities. Salthouse[4] has developed a general theory of age-related changes in fluid cognition. The theory contains two central components: a limited time mechanism and a simultaneity mechanism. According to Salthouse, changes in these mechanisms, at an elementary level, lead to changes that are observed in a variety of cognitive tasks. For example, the time available to perform higher-order cognitive operations would be limited by an increase in the proportion of the available time occupied by initial processing stages. Similarly, if initial processing is slowed, then the products of this processing may not be available simultaneously, as required by later operations.

Between the two boundaries of normal aging and genuine cognitive impairment is a broad transition state comprising gradations of cognitive change attributable to any of a host of etiologies, including benign effects of aging to early-stage AD. Over the last three decades, a variety of nomenclatures have emerged to describe the observed transitional memory state attributed to aging. The most commonly recognized terms include "benign senescent forgetfulness", "age-associated memory impairment" and, more recently, "mile cognitive impairment". These terms vary in subtle ways from one another. However, regardless of which terminology is used, all of these categorization schemas basically describe the same phenomenon, an admixture of mild memory problems that exceeds the range of normal cognition but falls short of being classified as dementia.

The term "benign senescent forgetfulness" (BSF) was originally coined by Kral[5] in the early 1960s to describe a form of mild memory impairment that occurred in the context of aging and did not appear to progress to dementia. In cohorts of elderly nursing home residents followed over 4 years, Kral *et al.*[6] observed that approximately 18% demonstrated a form of mild memory loss described as "subjective complaints of memory loss" and "difficulty in retrieving stored recent or remote information", such as names or other proper nouns. Frequently, these individuals were able to retrieve the "forgotten" information at a later time and they had well-maintained mental faculties otherwise. Compared to this group, another subgroup emerged with a more significant memory impairment, characterized by a prominent inability to retain recent information over even brief periods of time. These individuals typically had limited awareness of their difficulties and had tendencies to confabulate. This latter group, designated as "malignant memory loss", was associated with progression in symptoms to dementia, shorter survival times and increased mortality rates[6]. Kral believed that BSF was associated with physiological aging, whereas the more malignant form of memory decline was related to either vascular or degenerative disease.

The construct of BSF, although useful in succinctly describing the boundary conditions of aging, fell out of favor in later years, primarily due to a lack of standardization in the diagnostic criteria and the absence of clinical validation within representative elderly populations. The samples used in Kral's early work were criticized because of the inclusion of a very large proportion of chronic conditions, such as neurodegenerative diseases, cerebrovascular conditions and neuropsychiatric disorders. In more recent years, interest in aging and AD led to a re-emergence of attention on transitional memory states. In 1986, a workgroup convened under the auspices of the National Institute of Mental Health (NIMH) proposed the construct "age-associated memory impairment" (AAMI) to replace BSF. The new terminology had a firmer theoretical basis than its predecessor, with clinical and anatomical data to support its validity. The new nomenclature also improved upon BSF in that it included well-delineated standardized diagnostic criteria. The latter feature rendered the

new terminology more amenable to cross-laboratory investigation and potential intervention through pharmaceutical treatment trials[7].

Briefly, the criteria for the AAMI diagnosis includes: (a) the presence of subjective memory decline in an individual over the age of 50; (b) objective evidence of memory loss on standardized testing of memory function; (c) adequate intellectual function; and (d) the absence of global cognitive decline (i.e. dementia) or other disorders that could account for the symptoms. Although similar in form to the types of criteria used in arriving at other neurological diagnoses, such as AD and vascular dementia[8], the definition of AAMI differs in its specification of strict psychometric cut-points for the demonstration of memory loss and the absence of dementia. A patient diagnosed as AAMI must: (a) perform at least one standard deviation below the mean (for young adults) on at least one standardized test of memory function (e.g. Logical Memory from the Wechsler Memory Scale); and (b) demonstrate the absence of dementia, defined by normal performance on mental status screening using another psychometric measure, the Mini-Mental State examination (MMSE; a score of 24 or higher required).

The approach to defining the memory loss of aging based on a psychometric algorithm has been challenged on several grounds[9,10]. One of the main issues raised is the potential for diagnostic unreliability, particularly the threat of high false-positive rates, because the criteria rely on the results of a single memory test rather than on a consistent pattern of memory deficit. Spuriously low scores on a memory test (such as on the proposed use of the Logical Memory subtest) can be obtained for any of a variety of reasons. Similarly, patients with bona fide disorders may score quite well on the test but manifest difficulties in everyday life and on more tasking neuropsychological procedures. Related to this point, the criteria do not take into account individual differences in performance (e.g. effects of low education opportunities) or any of a variety of conditions that may alter performance and result in the mistaken impression of memory deficits, such as test anxiety or mood disorders. Finally, the choice of psychometric cut-points in the criteria for AAMI are criticized as insensitive. Dementias, particularly in early but clinically diagnosable stages, cannot be satisfactorily ruled out with MMSE scores of 24 or higher. Beyond these criticisms there is an even more fundamental concern that relates to the validity of AAMI as a process distinct from AD and other dementias. There is still considerable debate as to whether serious memory loss in the absence of dementia is actually a prodromal form of AD. The provision of an acronym, along with diagnostic criteria, implies that AAMI is an independent process associated with normal aging. However, much like its predecessor, BSF, there is ambiguity in the relationship between AAMI and AD. In fact, the similarity between the two conditions with respect to the underlying pathophysiology and proposed mechanisms for drug action suggest that AAMI is either a risk factor for AD or a mild, prodromal form of the illness. Despite these limitations, the notion of AAMI has advanced studies of aging by providing uniform criteria which could be applied across multiple sites. In so doing, the AAMI construct has allowed useful cross-study comparisons of the memory loss seen in the later decades of life.

Recently, studies from the investigative team at the Mayo Institute Alzheimer's Disease Center have suggested an alternative nomenclature for patients with memory impairments of aging, suspected to include substantial numbers of patients with preclinical AD[11]. These investigators refer to the boundary between normal aging and dementia as "mild cognitive impairment" (MCI), and characterize its clinical characterization and outcome. Unlike the terms AAMI and BSF, MCI is not considered benign and is instead viewed as being a risk factor or transitional state between normal aging and AD. This premise has some empirical support, including incidence data suggesting that there is a significant conversion rate from MCI to AD of approximately 12–15%/year (in line with other studies suggesting 50% conversion in 5 years). Normal controls, by contrast, convert to AD on an average of 1–2%/year. Because of the care devoted towards empirically defining the borderline condition of AD and aging, the "MCI" terminology is now growing in general acceptance and is becoming the standard nomenclature used by AD investigators involved in preclinical AD studies. It is still unclear whether all patients with symptoms conforming to MCI will convert to AD. Most likely the group of patients have some heterogeneity to their symptoms, reflecting multiple physical or medical causes (e.g. cardiovascular disease, diabetes, pulmonary conditions, etc.). With continuing progress in the identification of the underlying neuronal mechanisms of cognitive decline within normal aging, more clarity will be achieved in separating the various types of age associated memory conditions. This information is critical for secondary prevention efforts in preclinical AD.

Minor Cognitive Impairment

Karen Ritchie and Jacques Touchon
INSERM E99-30, Montpellier, France

Normal cognitive functioning in the elderly has commonly been conceptualized as the range of performance found in persons without identified pathology. Comparisons of mean performance between age cohorts show decrement with increasing age, which has been attributed in the past to normal physiological ageing processes. So-called ageing-related cognitive impairment, while being considered "normal", nonetheless has been of interest to clinicians because of the physical dependency it engenders, and as such it has been given independent nosological status. A number of concepts have been proposed to describe this tail-end of the normal cognitive range, beginning with the notion of "benign senescent forgetfulness", first proposed by Kral[1]. The publication of formal diagnostic criteria for minor cognitive impairment as "age-associated memory impairment" (AAMI) was undertaken by Crook *et al.*[2] for the National Institute of Mental Health. AAMI refers to subjective complaints of memory loss in elderly persons verified by a decrement of at least one standard deviation on a formal memory test in comparison with means established for young adults.

As memory impairment in the elderly is more commonly observed to be accompanied by deficits in other areas of cognitive performance, an alternative concept, ageing-associated cognitive decline (AACD), has been proposed by the International Psychogeriatric Association in collaboration with the World Health Organization[3]. AACD refers to a wider range of cognitive functions (attention, memory, learning, thinking, language and visuospatial function), and is diagnosed by reference to norms for elderly subjects. Application of AACD and AAMI to elderly persons within the general population suggests that they are distinct clinical entities, the latter referring to a more severe state of impairment[4].

More recently, recognition that the wide variability in cognitive functioning observed in the normal elderly may be due at least in part to the inclusion in this group of persons with prodromal dementia or other sub-clinical syndromes has led to the generation of alternative formulations, which situate minor cognitive impairment as potential pathology, for which the clinical response should be therapeutic rather than palliative. Within the 10th revision of the International Classification of Diseases (ICD-10)[5], criteria are given for "mild cognitive disorder" (MCD), which refers, like AACD, to a broader range of cognitive disorders than memory, demonstrable by formal neuropsychological testing and hypothetically attributable to cerebral disease or damage or to systemic physical disease known to cause dysfunction. MCD is thus construed as being secondary to physical illness or impairment, excluding dementia, amnesic syndrome, concussion or post-encephalitic syndrome. MCD is also applicable to all ages, not just the elderly. Early attempts to apply MCD criteria to population studies of elderly persons has so far met with limited success, which has cast doubt on the validity of MCD as a separate nosological entity[22]. On the other hand, Gutierrez *et al.*[6], arguing for the inclusion of a similar category in DSM ("mild neurocognitive disorder") have reviewed numerous studies implicating diverse forms of underlying pathology, in which such a nosological category would have been appropirate.

Early evidence that elderly persons with minor cognitive disorder may be at high risk of developing senile dementia has led to the development of the concept of "mild cognitive impairment" (MCI)[7]. MCI has provoked considerable interest amongst clinicians and the pharmaceutical industry, as it refers to a much larger potential therapeutic target group than senile dementia. As such, it is likely to become a more widely-adopted concept than its predecessors. The essential feature of MCI is that it is a pathological state that is potentially progressive. Beyond this, specific diagnostic criteria found in the current literature are inconsistent. Petersen *et al.*[7] initially refer to "complaints of defective memory" and "demonstration of abnormal memory functioning for age", with normal general cognitive functioning and conserved ability to perform activities of daily living. A later definition refers to "memory impairment beyond that expected for both age and education level"[8]. Krasuki *et al.*[9] refer to cognitive impairment with a score of 20 or more on the MMSE, and Zaudig[10] defines MCI as a score of more than 22 on MMSE or 34–47 on the SIDAM dementia scale. Others have referred to criteria based on the Clinical Dementia Rating Scale or the Global Deterioration Scale scores[11,12].

A central problem in the definition of MCI has been whether or not it should be confined exclusively to isolated memory impairment. Petersen *et al.*[8] specify that in MCI general intellectual functioning should be preserved, and that only memory should be affected, as it is the restriction of the impairment to amnesic abilities which differentiates the syndrome from AD. Isolated memory impairment was observed by the authors in a series of 76 MCI subjects; however, this appears to have been part of the diagnostic criteria for entry into the study, so that the situation is somewhat circular. Apart from the general problem of cognitive domain specificity in neuropsychometric testing (i.e. ascertaining that poor performance on a memory task is purely related to memory and does not implicate other functions, such as attention and language comprehension), other researchers have noted that subjects with MCI, although primarily having memory complaints, also commonly show deficits in other cognitive domains[11–14]. If the concept of MCI is

extended to include areas of cognitive impairment other than memory, then it may be considered to be identical to that of AACD, except for the underlying assumption that it is a potentially pathological, progressive syndrome rather than a feature of normal ageing.

To what extent may MCI be considered a prodromal phase of AD? A number of studies have suggested a significantly elevated risk of dementia in MCI subjects, with estimates of 10–15%/year of MCI subjects developing dementia to 100% over 4 years[8,9,14–17]. These studies are, however, all small hospital-based series. Risk factors for progression to dementia derived from larger-scale studies are ApoE 4, higher age, fine motor deficit and lower premorbid IQ[8,12,18].

A number of studies have described neurological changes in CT studies of MCI that distinguish it from normal ageing and senile dementia[9,14]. The principal characteristic observed in these studies is temporal lobe atrophy. Celsis *et al.*[19] (1997) report reduced parietal–temporal perfusion and left/right parietal–temporal asymmetry using SPECT in MCI. The observed hypoperfusion levels were found to be intermediate between those found in normal and AD subjects. Julin[20] used aligned SPECT and MRI images to compare MCI with early AD. AD patients were found to have atrophy and cerebral blood flow (CBF) reduction in both medial temporal and temporoparietal regions, whereas MCI showed significant reduction in CBF without atrophy in the temporoparietal region only. Jelic *et al.*[21] have used quantified EEG to demonstrate similarities between AD and MCI that differentiate both groups from the normal elderly on temporoparietal coherence and α and θ relative power. These findings suggest that MCI and AD have similar anatomical loci, with MCI being principally differentiated by the degree of impairment, and functional rather than structural change.

In a 3 year follow-up study, McKelvey *et al.*[17] reported that 64% of MCI subjects had abnormal SPECT scans at baseline; 53% of this cohort developed dementia, but of those developing dementia only 67% had initially abnormal scans, giving a positive predictive value of only 50%. On the other hand, Johnson *et al.*[15] have demonstrated a clear progression from MCI to dementia, based on SPECT perfusion levels from four regions; the hippocampal–amygdaloid complex, the anterior and posterior cingulate and the anterior thalamus. The authors conclude that, with semi-quantitative analysis and a spatial resolution sufficient to detect perfusion in limbic structures, it is possible to differentiate MCI from AD.

In conclusion, a number of nosological entities have been proposed to describe minor cognitive disorders occurring in elderly persons without dementia. MCI will probably evolve as one of the most important concepts in this area, with its underlying assumption that cognitive disorders in elderly persons are potential pathologies for which therapeutic care should be sought, rather than inevitable features of the normal ageing process. The concept appears to be almost identical to that of AACD, apart from its supposition of underlying pathology, but presently lacks clear operational criteria for either research or clinical application.

Alzheimer's Disease: One or Several?

C. Holmes and A. Mann
Institute of Psychiatry, London, UK

The current research diagnostic criteria for psychiatric illness, DSM-IV[1] and ICD-10[2] have evolved from a clinically descriptive exercise to an operationally defined procedure with a sharp demarcation between disease categories. In studies of dementia, diagnostic criteria with a hierarchical approach to diagnosis have also been widely adopted, in which the probability of a diagnostic subtype of dementia being present in a subject is also specified[3–5]. Subjects who fulfil clinical diagnostic criteria for probable disease are considered to have a purer form of the disease than those fulfilling the possible diagnostic category alone. This categorical approach aims to maximize differences between cases so that they are cleanly diagnosed. Thus, the presence of a delirium excludes the diagnosis of dementia, and the presence of cerebrovascular disease debars the diagnosis of probable Alzheimer's disease (AD). So widespread is the use of these diagnostic criteria that it is now almost impossible to practise clinical psychiatry, let alone get research findings published, without reference to them.

Clearly, this approach has its uses. It enables psychiatrists from different cultures to know, within the restraints of the diagnostic criteria, what collection of phenomenology or associated pathology they are talking about. An expertise (and associated research projects) can be developed within these diagnostic categories.

However, there are problems with such an approach and these are particularly clear in the area of dementia research. Thus, a categorical approach to diagnosis can lead to the exclusion of a large and interesting group of patients who do not fall into neat divisions. Such an approach emphasizes research into differences rather than similarities, between diagnostic categories. Finally, the assumption that clinical diagnostic categories have biological meaning is questionable.

In dementing illness, mixed pathologies are common. Indeed, the presence of vascular or Lewy body pathology, in the absence of other pathology, is relatively rare[6]. The reasons why various pathologies coexist could give important clues to the aetiology of both. However, for example, examination of patients fulfilling NINCDS–ADRDA diagnostic criteria for probable AD will lead to the exclusion of patients who have vascular risk factors, and so their importance in the development of AD pathology will be underestimated[7]. Common risk factors that are likely to be important in the development of AD and vascular disease have been recently reviewed[8], with associations found between AD and atherosclerosis, smoking, type 2 diabetes and high cholesterol. The mechanisms of such a link are not yet established. Does vascular disease play a part in the promotion of AD pathology or its presentation? Do common factors, such as insulin resistance, oxidative stress or cytokine activation, underlie both pathologies? Clearly, the examination of mixed cases in research studies would be beneficial in understanding common aetiological mechanisms.

The separation of some diagnostic categories lends an emphasis to differences where in fact greater similarities exist. Dementia and delirium, like the common subgroups of dementia, often coexist and also share many similar clinical and biological features. This finding is, ironically, emphasized by the demarcation of one subgroup of dementia, dementia with Lewy bodies, which has clinical characteristics such as prominent attentional deficits, hallucinations and fluctuating cognition that can make differentiation from delirium, particularly in initial presentation, very difficult. Rather than emphasize differences, another approach would be to accept the clinical similarities and to examine in more detail common epidemiological factors and pathological mechanisms of action, such as acetylcholine depletion and cytokine activation[9].

The adoption of clinical diagnostic criteria often presumes that a group of individuals, having reconciled a number of different opinions of varying political strength, have been able to define a single biological entity on the basis of its clinical features. Clearly, this is highly unlikely. Indeed, in dementia research (where we are fortunate in having generally agreed neuropathological hallmarks by which this hypothesis can be tested) it can be seen that the application of clinical research diagnostic criteria to a community-based sample of patients with dementia suggests that, while they are efficient in identifying pathology *per se*, they are notably less efficient when other pathologies are present[6].

In summary, whilst clinical diagnostic criteria have their uses, they also have their limitations. A broader perspective is needed, which can encompass research into the common aetiological mechanisms that explain the existence of common clinical or pathological phenomena across, and between, different clinical diagnostic categories.

Prognosis of Dementia

Barry Reisberg, Alan Kluger and Emile Franssen
Aging and Dementia Research Center, New York, USA

Dementia occurs on a continuum with the cognitive changes of normal aging and with mild cognitive impairment (MCI)[1,2]. Also, the process of dementia proceeds for many years after mental status assessments and conventional psychometric measures have reached floor (bottom) scores. Consequently, a clinically meaningful and useful description of the prognosis of dementia requires measures that are capable of spanning this vast cognitive continuum. Two kinds of measures that have been found to be particularly useful in describing this continuum and associated prognostic features are global assessments and assessment of the progressive functional course of brain aging and dementia. Two specific measures that have been found to be particularly useful in this regard are the Global Deterioration Scale[3] and the Functional Assessment Staging (FAST) procedure[4] (*see* Tables 1 and 2).

In a recent longitudinal study of more than 200 normal aged and MCI subjects followed over a mean interval of 4 years, the overall accuracy of GDS stage assignment at baseline (i.e. GDS stage 1, 2 or 3) in predicting subsequent decline to dementia was 81%[5]. In another longitudinal study of more than 100 community-residing patients with probable Alzheimer's disease (AD), who were followed over a mean interval of nearly 5 years, the correlation between change in GDS stage and time elapsed was 0.48, the correlation between change in FAST stage and time elapsed was 0.45, and the correlation between change in MMSE score and time elapsed was 0.32[6]. Consequently, the GDS and FAST measures each individually explained approximately twice the variance in AD temporal course of that accounted for by MMSE change. Furthermore, the GDS and FAST measures to some extent accounted for independent temporal variance. Consequently, these staging procedures (the GDS and FAST measures) together explained 28% of the variance (corresponding to a multiple regression correlation of 0.53), whereas change on the MMSE accounted for only 10% of variance (corresponding to a correlation of 0.32). This latter variance in the MMSE was entirely subsumed within that of the change on the GDS and FAST assessments.

What these statistics mean is that, with the staging procedures outlined in Tables 1 and 2, we can much more accurately chart the boundaries of normal aging and progressive AD and much more accurately predict the course of AD than with mental status assessments. The staging procedures also have the advantage of being clinically meaningful. This section briefly outlines the boundaries and prognosis of normal brain aging and progressive dementia, especially the dementia of AD, in terms of global, functional and traditional mental status assessments.

NORMAL BRAIN AGING

Although many, and perhaps most, persons over the age of 65 experience at least subjective cognitive complaints, many aged individuals have neither subjectively nor objectively manifest decrements in cognitive functioning. On the GDS and FAST measures, these individuals are in Stage 1. Current data indicates that the prognosis for these persons may be better than that for equivalently aged subjects with subjective complaints[5,7]. Clearly, the general prognosis for these persons is for continued healthy cognitive functioning.

AGE-ASSOCIATED MEMORY IMPAIRMENT

This entity is most clearly and usefully defined as one in which individuals experience subjective complaints of impairment, but in which even subtle deficits are absent upon clinical evaluation[8]. Although this condition (Stage 2 on the GDS and FAST scales), is largely benign, a recent longitudinal study found that nearly 15% of more than 100 subjects at a mean baseline age of approximately 70 years at this stage declined to a dementia diagnosis over a 4 year follow-up interval[5]. This rate of decline is higher than would be anticipated from current incidence data[9]. This rate of decline is also consistent with a recent study of Geerlings *et al.*[7], which concluded that the presence of memory complaints in an otherwise normal elderly population is associated with an increased risk of subsequent dementia.

MILD COGNITIVE IMPAIRMENT

At the present time, the precise definition of this entity remains quite fluid[10]; however, the initial definition employed by Flicker *et al.*[1] remains quite useful in understanding the nature of this condition and its associated prognosis. Flicker *et al.* defined this condition as the equivalent of GDS and FAST Stage 3. This is a stage in which subtle deficits are manifest on a careful clinical interview. These subtle deficits are generally of sufficient magnitude to interfere with complex occupational and social tasks. Studies indicate that many of these subjects develop overt dementia when followed after some years. For example, Kluger *et al.*[5] found that about two-thirds of more than 85 subjects followed at this stage manifested dementia when followed after 4 years.

DEMENTIA

The prognosis of dementia varies with the nature of the dementing disorder. The major form of dementia is Alzheimer's disease (AD). The prognosis of AD is described in Tables 1 and 2 in terms of progression of clinical global changes, mental status changes and functional changes. The progression of cerebrovascular dementia is generally quite similar to that shown for AD, with two major caveats: (a) cerebrovascular dementia has been shown to have a somewhat increased risk of death and morbidity than AD[11]; and (b) overt strokes will produce a somewhat different clinical picture and course from that shown in Tables 1 and 2. Similarly, it has been noted that AD patients who develop significant cerebrovascular disease with the progression of their condition, have a significantly more rapid illness course than AD patients who do not develop cerebrovascular dementia[6].

Lewy bodies occur in approximately 15–25% of dementia cases. However, in a great majority of these cases there is co-existing AD or cerebrovascular dementia. In these cases with Lewy bodies in addition to AD and/or cerebrovascular dementia, the clinical presentation and course appear to be those of AD or cerebro-

Table 1 Global Deterioration Scale (GDS) for age-associated memory impairment and Alzheimer's disease[3] (choose the most appropriate global stage based upon cognition and function)

GDS stage	Clinical characteristics	Diagnosis and prognosis	Approximate mean MMSE[5,25,26]
1	*No subjective complaints of memory deficit*. No memory deficit evident on clinical interview	Normal adult	29–30
2	*Subjective complaints of memory deficit*, most frequently in following areas: (a) Forgetting where one has placed familiar objects (b) Forgetting names one formerly knew well No objective evidence of memory deficit on clinical interview No objective deficit in employment or social situations Appropriate concern with respect to symptomatology	Age-associated memory impairment (sometimes termed "normal aged forgetfulness" or "age-associated cognitive decline"). 15% develop dementia within 4 years[5]	29–30
3	*Earliest clear-cut deficits*. Manifestations in more than one of the following areas: (a) Patient may have become lost when traveling to an unfamiliar location (b) Co-workers become aware of patient's relatively poor performance (c) Word- and/or name-finding deficits become evident to intimates (d) Patient may read a passage or book and retain relatively little material (e) Patient may demonstrate decreased facility in remembering names upon introduction to new people (f) Patient may have lost or misplaced an object of value (g) Concentration deficit may be evident on clinical testing Objective evidence of memory deficit obtained *only with an intensive interview* Decreased peformance in demanding employment and social settings Denial begins to become manifest in patient Mild to moderate anxiety frequently accompanies symptoms	Mild cognitive impairment. Two-thirds develop dementia within 4 years[5]	25–27
4	*Clear-cut deficit on careful clinical interview*. Deficit manifest in following areas: (a) decreased knowledge of current and recent events (b) may exhibit some deficits in memory of one's personal history (c) concentration deficit elicited on serial subtractions (d) decreased ability to travel, *handle finances*, etc Frequently no deficit in following areas: (a) orientation to time and place (b) recognition of familiar persons and faces (c) ability to travel to familiar locations Inability to perform complex tasks Denial is dominant defense mechanism Flattening of affect and withdrawal from challenging situations	Mild AD. Mean duration, 2 years	20
5	*Patient can no longer survive without some assistance. Patient is unable during interview to recall a major relevant aspect of his/her current life*, e.g.: (a) Address or telephone number of many years. (b) Names of close members of his/her family (such as grandchildren). (c) Name of the high school or college from which he/she graduated. Frequently, some disorientation to time (date, day of the week, season, etc.) or to place An educated person may have difficulty in counting back from 40 by 4s or from 20 by 2s Persons at this stage retain knowledge of many major facts regarding themselves and others They invariably know their own names and generally know their spouse's and children's names They require no assistance with toileting or eating, but may have difficulty in choosing the proper clothing to wear	Moderate AD. Mean duration, 1.5 years	14
6	*May occasionally forget the name of the spouse upon whom they are entirely dependent for survival*. Will be *largely unaware of all recent events and experiences in their lives* Retain some knowledge of their surroundings; the year, the season, etc. May have difficulty counting by 1s from 10, both backwards and sometimes forwards *Will require some assistance with activities of daily living*: (a) May become incontinent (b) Will require travel assistance but occasionally will be able to travel to familiar locations Diurnal rhythm frequently disturbed Almost always recall their own name Frequently continue to be able to distinguish familiar from unfamiliar persons in their environment Personality and emotional changes occur. These are quite variable and include: (a) Delusional behavior, e.g. patient may accuse his/her spouse of being an imposter; may talk to imaginary figures in the environment, or to his/her own reflection in the mirror (b) Obsessive symptoms, e.g. person may continually repeat simple cleaning activities (c) Anxiety symptoms, agitation, and even previously non-existent violent behavior may occur (d) Cognitive abulia, e.g. loss of willpower because an individual cannot carry a thought long enough to determine a purposeful course of action	Moderately severe AD. Mean duration, 2.5 years	5
7	*All verbal abilities are lost over the course of this stage*. Early in this stage words and phrases are spoken but speech is very circumscribed. Later there is no speech at all—only unintelligible vocalizations *Incontinent; requires assistance in toileting and feeding* *Basic psychomotor skills (e.g. ability to walk) are lost with the progression of this stage*. The brain appears to no longer be able to tell the body what to do. Generalized and cortical neurologic signs and symptoms are frequently present.	Severe AD. Mean time to demise 2–3 years; potential for survival, 7 or more years	0

Table 2 Functional assessment stages (FAST) and time course of functional loss in normal aging and AD*

FAST stage	Clinical characteristics	Clinical diagnosis	Estimated duration of FAST stage or substage in AD†
1	No decrement	Normal adult	
2	Subjective deficit in word finding or recalling location of objects	Age-associated memory impairment (normal aged forgetfulness)	
3	Deficits noted in demanding employment settings	Mild cognitive impairment	7 years**
4	Requires assistance in complex tasks, e.g. handling finances, planning dinner party	Mild AD	2 years
5	Requires assistance in choosing proper attire	Moderate AD	18 months
6a	Requires assistance dressing	Moderately severe AD	5 months
6b	Requires assistance in bathing properly		5 months
6c	Requires assistance with mechanics of toileting (such as flushing, wiping)		5 months
6d	Urinary incontinence		4 months
6e	Fecal incontinence		10 months
7a	Speech ability limited to about a half-dozen words	Severe AD	12 months
7b	Intelligible vocabulary limited to a single word		18 months
7c	Ambulatory ability lost		12 months
7d	Ability to sit up lost		12 months
7e	Ability to smile lost		18 months
7f	Ability to hold head up lost		12 months or longer

*Adapted from Reisberg[27]. Copyright © 1984 by Barry Reisberg, M.D.
†In subjects without other complicating illnesses who survive and progress to the subsequent deterioration stage.
**Although the potentially observed duration is 7 years, patients are generally past the midpoint of this stage when brought for evaluation.

vascular dementia. Only in a small minority of dementia cases, an estimated 4% of the total, do Lewy bodies appear independently of AD and/or cerebrovascular disease. In these cases, a distinctive clinical picture has been described, marked by fluctuating cognition, recurrent well-formed visual hallucinations, and parkinsonian features[12]. There is a relatively rapid progression of the dementing disorder in Lewy body dementia, in comparison with AD.

Other forms of dementia that occur earlier, as well as in later life, including frontotemporal dementia and Creutzfeldt–Jakob disease, also differ in presentation and course from the classical AD course outlined in Tables 1 and 2. This AD course, which applies to the great majority of dementia patients, is described in Tables 1 and 2 and very briefly outlined below.

Mild AD

Stage 4 on the GDS and FAST scales, this stage has a mean duration of 2 years. Although overt deficits are present on assessment, patients are still capable of independent community survival, although the ability to manage financial and similarly complex affairs becomes compromised. Patients at this stage generally endeavor to conceal their deficits, just as humans in general endeavor to appear intelligent and try to present themselves well. This concealment may also take the form of denial, whereby the patient tries to hide his/her problems from him/herself. Another defense mechanism is a flattening of affect, in which the patient is less participatory in social situations and appears to become more quiet and withdrawn. Medications frequently prescribed for AD patients, such as the SSRI antidepressants, may mask these otherwise common symptoms of affective flattening, making these patients appear even more overtly normal, despite their cognitive deficits.

Moderate AD

Stage 5 on the GDS and FAST scales, this stage has a mean duration of 1.5 years. Patients at this stage have deficits that are sufficient to interfere with independent community survival. Patients who are left alone in the community at this stage are either assisted by neighbors, relatives or others, or they are preyed upon by less scrupulous persons in our society. Functionally, persons at this stage develop incipient deficits with basic activities of daily life. More specifically, patients begin to require assistance in choosing the proper clothing to wear for the season and/or the occasion. Without assistance, patients will, for example, wear the same clothes day after day. A variety of emotional responses develop in an attempt to cope with the deficits in this stage. These commonly include suspiciousness, anger and false beliefs[13]. The magnitude of these emotional responses is probably dependent in part on the social supports provided to the patient. Patients who perceive themselves as secure may present themselves in socially appropriate ways at this stage and may successfully conceal their deficits in social situations.

Moderately Severe AD

Stage 6 on the GDS and FAST scales, this stage has a mean duration of 2.5 years. Patients at this stage develop deficits in basic activities of daily life. First, difficulties with dressing and bathing occur. Patients will put on clothing in the improper order or backwards unless assisted. At about the same time, patients develop difficulties with independently adjusting the shower- or bath-water temperature. With the progression of this stage, problems with independent toileting and independent continence occur. Collectively, these problems are such that not only can the patient not survive independently but, additionally, spouses or other caregivers begin to require additional help to manage the patient in a community setting. Emotional problems in the patient peak in this stage and generally include aggressivity and activity disturbances[13]. The newer atypical neuroleptics can be very useful in managing the overt emotional reactions in the patient, as can psychological non-pharmacological, management approaches[14,15].

Severe AD

Stage 7 on the GDS and FAST scales, this is the final stage of AD. Patients succumb throughout the course of this stage; however, the mean time to demise is about 2–3 years. Patients who progress to the final substage of severe AD, may survive for 7 or more years in this stage. Speech ability breaks down prior to the advent of this stage in the course of AD, and patients emerge in the final seventh stage with very limited remaining speech; generally a half dozen or fewer intelligible words are discernible in the course of an intensive interview in which numerous queries are presented to the patient. With the progression of this stage, speech becomes even more circumscribed. Ambulatory ability may be lost prematurely; however, after speech is lost, the ability of the patient to walk is inevitably lost. Subsequently, the ability to sit

up independently, to smile, and to hold up the head independently are lost. Each of the six functional substages in this final seventh stage of AD lasts a mean of a year or longer. Studies have shown continuing cognitive, neurological, and neuropathological changes over the course of this final AD stage[16–19]. Throughout this stage, patients require continuous assistance for survival. Even with assistance, patients are very susceptible to disability. For example, physical deformities known as contractures occur in about 40% of patients in the early portion of this stage and become nearly universal as this stage progresses[20]. Overt behavioral symptoms become less manifest in this stage and the need for psychotropic medications steadily declines[13]. Patients commonly succumb to conditions such as pneumonia, resulting from aspiration or stroke or infections from decubiti or other sources.

Retrogenesis

It has been noted that the progression of losses in many domains in AD, and also in select other dementing disorders, reverses the normal human developmental pattern, a phenomenon which has been termed "retrogenesis"[21,22]. This process is particularly striking with regard to the progression of functional losses in AD, which precisely reverse the order of functional acquisition from birth to the adult (Table 3). Cognitive changes also reverse the normal human developmental patterns. For example, the correlation between the MMSE and mental age has been found to 0.83[23]. Neurologic reflexes have been found to be approximately as robust markers of AD course as the same reflexes are useful as markers of normal infant and child development[24]. Other physiological and pathological phenomena in AD also appear to follow a retrogenic pattern[21]. Because of these striking retrogenic relationships, the stages of AD can be usefully understood in terms of corresponding developmental ages (DAs). The management and care needs, and many AD emotional changes can be understood on the basis of the DA model[22].

Acute Management of Dementia

Brice Pitt

St Mary's Hospital, London, UK

Alzheimer's disease (AD) and senile dementia of the Alzheimer type (SDAT) have an insidious onset and a prolonged course (sometimes running for 20 years); so, on the face of it, the need for acute management should seldom arise.

Indeed, perhaps for many sufferers—the "silent majority"—it may not. Some old people become ever more forgetful and adapt gradually and graciously to their limitations, while their families and friends perceive them simply as starting to show their age rather than as demented. They give them a little more help every few months, which is accepted appreciatively as appropriate. The old person may receive a lot of care at home, or move to live near or with one of the family, or agree that it would be wise to go into sheltered housing or a home, until in due course a gentle death brings life to a dignified end.

However, the course in those referred to professional services—general practitioners, social workers, geriatricians and psychogeriatricians—is often less tranquil. Usually such patients have been dementing for a year or two and the referral has been precipitated by a crisis.

CRISES

Such a crisis could be when the family doctor is telephoned by anxious and irate relatives who have visited their parent over the weekend and found things worse than when they last visited 2 months previously, or the belated awareness that he/she is not coping very well and that a long weekend, like Christmas or Easter, is imminent and that there could be problems. Relatives are usually very caring and the culture supportive, but in the developed nations families are small and dispersed and both men and women are employed, while the elderly population is large—over the age of 65 in Britain[1]; so to take care of a dementing elder at a distance requires considerable adaptation.

Crises also arise where the demented people react to their disorder not with insight, but with robust denial. These are exemplars of the "Dylan Thomas syndrome":

> Do not go gentle into that good night;
> Rage, rage against the dying of the light!

They age disgracefully, fighting the implications of a failing memory, mind and body every step of the way, stubbornly independent unto death unless society intervenes, either by overruling their rights or by using some form of mental health legislation. These denying demented patients are a huge challenge to the health and social services.

Traditionally, the dementias may be dichotomized into the presenile and senile forms, or Alzheimer's and non-Alzheimer's. However, for the purposes of this chapter, the most practical division is into those who live with others and those who live all alone. The prognosis for survival of the latter, even if given good domicilary support, is far worse[2].

LIVING ALONE

Demented people who live alone may do so because they are single, divorced or widowed and without children. Widowing can be an acute event, and one of the crises in dementia is when a key carer dies, leaving the dependant not only emotionally bereft but also suddenly deprived of his/her main prop. An acute grief reaction is compounded by the abrupt removal of a principal support. The work of grieving is complicated by forgetting or denying that the loss has taken place. Plans for the future may be undermined by the fitful expectation that the lost one will return.

There may be personal as well as social factors in a demented person's living alone. Some people react to the early intimations of their disorder by withdrawing and leading a very simplified, limited existence. Finding it an effort to sustain conversation with neighbours, friends and even family, they adopt an isolated, frugal life. Those who deny that they have any difficulties are unlikely to accept the help that is willingly offered. "I don't want anyone coming to my house to do my housework and shopping—poking their nose in where it's not wanted". "Are you saying I can't look after myself? I've managed very nicely for all these years?" "Why would I want to come and live with you (or in sheltered housing, or in a home)? I've got a perfectly good home of my own, thank you very much!" These denials are often made by people with a well-preserved, assertive personality, and enough retention of language to make their wishes plain (although without the hearing, comprehension, insight or will to listen to reason!).

Living alone with so devastating a disorder as dementia is evidently risky. Accidents occur easily in those who lack the foresight or the judgement to prevent them, and demented old people are consequently over-represented in general hospital wards. Drugs needed to control diabetes, heart failure, epilepsy or arthritis may be taken erratically or not at all, with serious consequences. Malnutrition is a hazard for those who cannot remember whether they have eaten or not, to draw their money or where they have put it, where and when to shop and for what, and what to do with what they may have bought if they can find it. Cold weather adds to the dangers of falls and hypothermia. Floods and conflagrations are always possible, and failings

in personal hygiene may amount in due course to alarming squalor.

LIVING WITH OTHERS

Dementia may develop in those already living with their family—a spouse or a son or (most often) a daughter. Crises then arise from the dependant's growing infirmity and the increasing burden on the carer(s)[3]. Acute exacerbations of the dementia intensify the strain. These may arise from:

- The swift progression of the dementia from one stage to the next[4]. This is said to be characteristic of multi-infarct dementia[5], but may also occur in Alzheimer's disease.
- Events affecting bodily health, such as heart failure, a urinary or respiratory tract infection, a fall leading, perhaps, to head injury; even impaction of faeces may all add to the patient's confusion.
- Depression may have a similar but more prolonged effect. Dementia is no protection against depression, especially where there is some preservation of insight[6].
- The dynamics of the household may have altered because of some comings or goings or change in the attitudes or well-being of one of its members. Marital strain can cause, as well as arise from, disturbed behaviour in a demented member of the household.

The demented person may have moved to be with family because of increased infirmity and dependency. Occasionally, one of the family moves in with the demented person, as when a son returns home after being divorced. Such a move may be the result of some critical failure in self-care—getting lost, having an accident, being bereft, coming out of hospital unable to cope. By moving, the demented person gains safety and security, but dependency increases, autonomy dwindles, friends and familiar haunts are now at a distance and the activities necessary for daily living are much reduced. The carer has gained peace of mind at the cost of privacy and some disruption of the household[7]. The arrival of a confused grandparent, repeating him/herself, disapproving and getting in the way, may be less than welcome to the carer's adolescent children. Also, confusion in the demented is commonly aggravated by a move, so the earliest days are not the easiest.

Occasionally the strain on carers can erupt into "elder abuse"[8]. This may take the form of physical violence, as well as angry outbursts and verbal abuse. The commonest form is when there has been mutual dependency between the demented parent and the abusing son or daughter, now at the end of his/her tether and feeling trapped in the situation.

HOSPITAL, SHELTERED HOUSING AND HOMES

Demented people are, because of their accident-proneness and deficiencies in self-care, far more prevalent among the elderly in general hospital wards than in the population at large[9]. Here their problems may be exacerbated by sudden admission, hasty and inadequate communication, the discomfort and disability of whatever they have been admitted with and sometimes, unfortunately, the indifferent, dismissive, patronizing and even hostile attitudes of staff, wary of another "social admission" or "bed-blocker"[10]. Medication may add to confusion by lowering blood pressure, causing drowsiness, or through anticholinergic side-effects. In the setting of a busy medical or surgical ward, an apparently able-bodied but deranged older person may be perceived as a threat—disturbing sick patients by being noisy and interfering—or an undue responsibility, liable to wander off and become lost. Consequently it is still not unknown for physical restraint—binding hands, body or feet, trapping the patient in a "geriatric" chair, using cot-sides—to be added to sedation[11].

A move into sheltered housing seems to have much to commend it for those who are now too forgetful and erratic to manage readily at home but not in need of full-time care. However, such a move is better made sooner than later. Otherwise, the strangeness of the new environment aggravates the confusion, and problems may arise in the use of the alarm cord or bell to call the warden, who is summoned frequently in error. Too often the stay in sheltered housing proves quite brief, before a further move into institutional care is necessary.

Although most demented people are in their own or relatives' homes, they are also major users of residential and nursing homes, some taking all comers, others specializing in the elderly mentally infirm ("EMI"). Even in ordinary homes, as many as 60–70% of the residents may be found to be demented[12]. Homes which were already looking after the old person before the onset of dementia usually cope very well, but where someone is admitted because of their dementia there may be clashes because the parties have not had time to get to know each other. Demented people can, of course, be difficult, demanding and highly irrational, but sometimes "it takes two to make a quarrel" and tactless, hasty, overbearing staff may provoke escalation of a minor dispute into a major row. Other problems that may arise from communal living include fights between residents, say where one accuses the other of going off with his/her belongings or of wandering into his/her room and interfering with the bedding (which may well be true!), and antisocial behaviour such as stripping, masturbation, sexual advances, noise and disgusting eating habits. Another crisis is that the money runs out for costly care and there are urgent demands to find the resident another place!

ACUTE MANAGEMENT

Acute problems may be lessened by early identification of the dementia, taking account of how it is managed at that time, who is (or may become) the key carer and designating a key worker to guide, advise and support that person. If no key carer is identifiable among family or friends one may need to be enlisted, such as a home help or a paid "good neighbour". Such arrangements are highly dependent on good, well-organized primary health care and social services, with support from voluntary agencies and a well-resourced psychogeriatric service, all working well together. A "case manager", generally someone with a background in nursing or social services may be the best person to assemble a "package of care"[13], but is more effective when the client is merely elderly and infirm[14] than significantly demented[15].

Where dementia is identified early as the result of a screening programme (e.g. for the over-75s)[16], some discretion as to how, when or, indeed, whether to impart that information. There is the possibility of an adverse reaction to the label "dementia"; the family may feel that the task of caring will prove too much—beforehand they thought they were just helping someone who was ageing normally—while demented persons may be distressed by the diagnosis. However, there is the possibility of involving them with the carers in plans for their future, to prefer one kind of management to another, make a will, give an enduring power of attorney and feel that they retain some control over their own destiny[17]. The advent of the oral anticholinesterases for Alzheimer's disease[18] demands informed consent to their use.

Key carers need respite before they feel burdened by their continuous responsibility. "Sitters-in" enable them to take a few hours out of the home alone. Meals on wheels and home helps should not be reserved solely for demented people living alone;

they ease the load on carers and help them to feel less alone with the problem. An incontinence service providing pads and collecting soiled sheets and garments for laundering is a huge help. Financial recognition of the work that has to be done in the form of an attendance allowance is often greatly appreciated, although the sum may not be great. Day hospitals and respite admissions have been demonstrated to reduce scores measuring stress and strain in carers[19]. Relatives' support groups, personal counselling by a community psychiatric nurse, social worker, psychologist or doctor and, where feelings in the household are running high, family therapy[20], may all have their place. It is important for the key worker to keep in touch with the situation, to be easily available and able to offer extra assistance, e.g. admission to hospital or a home, as and when that is needed. The credibility of the service is seriously jeopardized if the help that all recognize to be required cannot in fact be given.

An interesting field study in Cambridge[21] randomly divided demented people living alone or at home with others into those who received routine care and those who received extra home care. Extra care made no significant difference to those living with others, but those living alone were far more likely to be in a residential home 2 years into the study if they were getting extra care than if they were not! This was less a demonstration of the ineffectiveness of community care than an indication that those who received it were correctly placed where they needed to be at the appropriate time.

The demented who live alone are especially in need of close monitoring by the key worker. Those who will accept help are obviously an easier proposition than those who will not. The home help is the chief provider of "hands-on" care, and may be required from 2 h/week to 6 h/day (at which stage, of course, the cost is not negligible). Meals on wheels not only support nutrition but also provide regular human contact, as do lunch clubs, day centres and day hospitals for those who can make their way there or be taken to them. Community ("district") nurses may get patients up, bathe them, help them to bed and give their medication—but the supply of such skilled staff is not limitless. Reliable, trustworthy volunteers are useful in befriending, doing small chores and running errands. Financial arrangements need to be made with banks, post offices, lawyers, social workers and whoever either holds the power of attorney or has been nominated as the Receiver by such a body as England's Court of Protection[22].

Demented people seriously at risk who refuse help may occasionally be compelled into care or placed on a guardianship order under mental health legislation (UK)[22]. This, or the decision not to take such an action, is usually the result of a case conference, often convened by a social worker, and attended by relatives, neighbours, nurses, home helps and their organizers, the general practitioner, the psychiatrist and perhaps concerned volunteers, clergy and the police. Often the conclusion is that what cannot be achieved by persuasion cannot be achieved, so a close eye is to be kept on the subject of the conference until he/she becomes more willing to accept help, falls ill and goes into hospital or dies, or confounds expectations by living on in much the same state for years!

Staff in hospitals and homes need to be trained to give demented people proper care, by example and experience as well as by precept. The inculcation of respect is a good starting point—breezy, patronizing familiarity may give offence. It is important to learn not to take umbrage, to blame, to accuse of attention-seeking or provocation and to avoid futile arguments. A spacious, bright, cheerful environment and a full, appropriate programme, including some conversation, entertainment (a sing-song is much preferable to the ubiquitous television, but people should be free to opt out), exercise and bringing visitors into the regime help to prevent problems arising from boredom and inaction.

Alertness to health problems may prevent some of the exacerbation of confusion by physical illness. Depression afflicts not a few demented people, causing agitation and restlessness by day and night. A trial of antidepressant therapy is indicated, but the old antidepressants are too powerfully anticholinergic, sedative or hypotensive to be the first choice. Serotonin-specific reuptake inhibitors are to be preferred, and citalopram 20 mg daily has been shown to improve depressive symptoms in dementia in a placebo-controlled study[23]. Rarely, in those who appear severely depressed, are not eating and who may have a history of severe depression, there could be a place for electroconvulsive therapy.

A full day's activities reduce sleep problems (and patients can often catch up on their sleep by day) but carers need sleep, and the use of a hypnotic for a restless patient may thus be justified. None is ideal, but among those to be considered are temazepam, a very popular benzodiazepine, 20–40 mg (which may induce a hang-over); zopiclone, a cyclopyrrolone, 3.75–7.5 mg; chlormethiazole, a short-acting drug which occasionally causes sneezing, 250–500 mg, at night; or chloral hydrate, in tablet form (the equivalent of 414 mg in a tablet), one or two at night.

There is no perfect neuroleptic in old age psychiatry: all can cause as much trouble from side effects, notably drowsiness, extrapyramidal symptoms and falls, as any benefit they bring. Demented people seem particularly susceptible to such side effects and to tardive dyskinesia[24]. However, where the urgent control of a very disturbed patient is necessary in a setting where alternatives are not practicable, one of the major tranquillizers may be warranted[21]. The butyrophenone haloperidol, 5–10 mg i.m. or i.v. (often with procyclidine 10 mg through the same needle to prevent acute extrapyramidal reactions) is a most useful drug, and can be repeated up to 6-hourly. Once the acute crisis is over it may be replaced by one of the newer, "atypical" antipsychotics, risperidone (0.5–2 mg, twice a day), olanzepine (5 mg once or twice a day), with fewer extrapyramidal side-effects than haloperidol[25] and shown by meta-analysis[26] effectively to ameliorate symptoms of psychosis, aggression and agitation. Very popular, and reasonably safe, although quite sedative and anticholinergic, is thioridazine, 10–100 mg, up to four times a day.

Present and Future Treatments of Alzheimer's Disease

Lawrence J. Whalley[1] **and John M. Starr**[2]
[1]*University of Aberdeen and* [2]*University of Edinburgh, UK*

Modern theories of disease predict that, when valid diagnostic criteria are available and causes can be confidently ascribed to a disease condition, then effective treatments will be developed[1]. In clinical practice, the diagnosis of late-onset Alzheimer's disease (AD) is not supported by definitive diagnostic findings and no consensus exists on its causes. Currently, diagnosis depends on a cluster of neuropsychological features combined with the absence of other pathologies, identified clinically or by investigation. In those patients who present at a later stage, neuropsychological deficits are so severe and global that differentiation from other aetiologies is difficult. Moreover, the presence of other causes of cognitive decline, such as stroke, does not exclude AD; indeed, the prevalence of AD is far more common in people with stroke than would be expected by chance alone.

Observational longitudinal studies suggest that both genetic and environmental factors are important in early-onset AD[2]. Best estimates in late-onset AD are that genetic and environmental influences are approximately equal[3]. In early-onset AD genetic factors seem more important but at present can account for fewer than 10% of cases[4]. Known mutations that contribute to the causes of late-onset AD appear so far to be relatively infrequent[2,5] but genetic contributions to functional ability in late life are also established[6]. Genetic susceptibility factors are less well established; apolipoprotein E polymorphisms are best known and may influence the timing of the onset of AD in almost 50% of cases[7]. For many commentators, these sparse facts encourage the search for environmental factors that certainly contribute to the onset of dementia and, by extension, to the possible modification of those exposures. These interventions may slow or even prevent the onset of dementia. So far, however, no single factor or group of factors has been reliably confirmed as an environmental contributor to the risk of dementia. This situation is similar to the problems faced by specialists in old age medicine about 30 years ago. At that time, there was some concern about the accumulation of disabilities in old age, so much so that population projections predicted increasing longevity and an increased burden posed by large numbers of disabled old people[8]. One of the great successes of modern geriatric medicine was the postponement of the expected accumulation of disability into the final year of life. This in turn has reduced the period of dependency in old age, especially for men[9]. Prevention of disability was the key outcome of the interdisciplinary research programme one "successful ageing" in the USA[10]. Compression of disability and morbidity has been so great that the proportion of men aged 80 years in North America and Northern Europe with at least one disability halved between 1975 and 1995[11].

These reductions were achieved by preventative measures to detect and reduce environmental exposures in old people known to be at increased risk for vascular disease. Hypertension, smoking, diabetes, obesity and hyperlipidaemia proved susceptible to such interventions. Likewise, smoking reduction and improvements in air quality reduced the burden posed by respiratory disease and cancer. Reduction of disease incidence and subsequent improvements in well-being in old age have prompted some researchers to speculate that much of what is regarded as "ageing" is made up of at least two processes[12]. One process comprises the accumulated effects of disease and the acquired handicaps and disabilities of old age. The other is made up of at least one process, usually termed "intrinsic ageing". The nature and cause of intrinsic ageing processes are currently described using terms such as "the oxidative stress model" or "accumulated DNA damage" or "inefficient DNA repair". The formation of advanced glycated end products, the consequences of membrane lipid peroxidation and failure of immune surveillance are all included in current hypotheses concerning intrinsic ageing. However, given that the brain enjoys specific privileges, e.g. in terms of immuno-surveillance and neurons being naturally in a post-mitotic state throughout most of the lifespan, whether some general "intrinsic ageing" process applies to the central nervous system or is the same as that for other organs is questionable.

From the standpoint of dementia prevention and/or treatment, brain ageing research is now of pivotal importance to future progress. The success of modern geriatric medicine has been achieved largely by translation of epidemiological data into public health-based preventative programmes. This chapter first considers what is currently available to treat or prevent dementia. Second, it examines some of the potential for neuroprotection and dementia prevention and/or treatment provided by recent research findings in brain ageing. Third, lessons learnt from general medicine in the prevention of heart disease and cerebrovascular accidents will be considered. Fourth, future strategies proposed to slow or even prevent brain ageing and the characteristic features of AD will be briefly summarized.

CURRENT TREATMENTS

Who is Eligible for Treatment?

AD is the most frequent cause of late-onset cognitive impairment in the UK and probably affects around 350 000 people. Incidence

rates approximately double every 5 years (65–90), such that about 20–25% of those over 80 are affected. UK demographic studies predict that old people who are cognitively impaired will increase by 11% during 2001–2011. The prevalence of AD seems likely to double by 2050. All AD sufferers are currently regarded as potentially eligible for dementia treatment.

What Are the Benefits of Current Dementia Treatment?

Anti-dementia therapy benefits are now recognized to be wider than just the slowing or improvement of cognitive decline. Additional improvements include reduced disability, time to institutionalization and fewer acute medical or surgical emergencies. Disabilities place considerable burdens on health and social services and the incidence of disability increases with age. These burdens include needs for social support, especially in best use of available health services, problems of co-morbidity and institutionalization. In London, the Gospel Oak studies reported disability in 38% of community residents aged 65–74, 77% aged 75–84 and 96% aged 85+[13] and the overall prevalence of dementia was 9.8%. Predictions based on the MRC Cognitive Function and Ageing Study (MRC CFAS) suggest that people aged 65+ with severe disability will make up 2.2% and 3.9% of the population in 2011 and 2051, respectively[14]. In general terms, disability from whatever cause forecasts both mortality and prolongation of length of stay after admission to hospital.

The MRC CFAS provides further valuable information on the burden of health care linked to cognitive impairment. Cognitive impairment was detected in 38% of disabled people aged 65 years and in 46% of people in institutional care. Cognitive impairment also generates other health service demands, some not immediately obvious. For example, a reduction of dementia prevalence of 1–2% would reduce the number of hip fractures in the UK by 20 000/year[15,16].

The Anti-dementia Drugs

Currently available drugs are based on the established cholinergic deficits in AD and early recognition that these may be sufficient to explain "core" symptoms. There are no claims that current drugs do any more than provide symptomatic relief. Large-scale randomized placebo-controlled trial results are available for three anticholinesterase drugs: donepezil[17,18], rivastigmine[19,20] and galantamine[21,22]. These show that, in general, these drugs: (a) improve global outcome; (b) slow or arrest cognitive decline; and (c) improve activities of daily living. Carers also report that some troublesome behaviours, such as apathy and apparent responses to hallucinations or delusions, are helped by drugs of this type but as yet no satisfactory clinical trial data are available. There is a consensus to support a relatively enduring good cognitive response equivalent to an arrest of disease progression of about 9 months. This is not sustained, however, and is followed by a fairly rapid decline that reverses any earlier benefit. Primarily for this reason, most commentators agree that anticholinesterase drugs do *not* modify any underlying disease process.

The generality can obscure some quite remarkable and sustained improvements in a subset of patients. Almost half of AD patients show evidence of improvement and sustain that improvement for up to about 18 months. Within this group there is a small proportion (roughly around 1 in 12) who show very extensive improvements, sometimes sufficient to permit resumption of mentally effortful recreational pursuits. Unfortunately, there is no evidence that this group of high responders obtain long-term benefits. Such patients are highly encouraging in routine clinical practice and certainly help motivate and improve morale in dementia care teams.

This class of drugs is usually well tolerated. Common unwanted effects include cholinergic actions on the GI tract (nausea, vomiting and diarrhoea). Few data are available on the effects of these drugs on disability and institutionalization rates. Tacrine was one of the early antidementia drugs and is now discontinued. Patients receiving tacrine and remaining on doses greater than 80 mg/day may be less likely to enter a nursing home than those on lower doses or who have stopped the drug[23,24].

Cost Concerns

Although the licensing of cholinesterase inhibitors has introduced widely available drug treatment for AD for the first time, the costs of these drugs prohibits extensive use in less developed countries, where the greatest increase in numbers of people with AD is expected. Even within the UK there is considerable geographical variation in the availability of antidementia drugs. In part this remains attributable to poorly informed pessimism about dementia treatment, but the fact that much-needed pharmacoeconomic data were not collected in trials sponsored by the pharmaceutical industry must share part of the responsibility. Largely at the direction of regulatory authorities, the sponsors include clinically meaningful measures of competencies in daily living, and these have become the cornerstone of current recommendations to administer these drugs as widely as possible. At present, there is an impression that these drugs are "cost-beneficial" and reduce overall spending on services for dementia. If delay to institutional care is accepted as a valid proxy in economic analyses, the eventual conclusion seems likely to support their use[25]. Data from Canada indicate that the largest proportion of costs is attributable to institutionalization. Use of donepezil for mild-to-moderate AD was associated with lower 5 year costs and less time spent with severe AD when compared with the alternative of usual care[26]. In a retrospective cost analysis in Dutch patients with Alzheimer's disease who were being cared for at home at the start of the study period, treatment with donepezil did not increase overall direct medical costs[27].

To obtain an improvement of four points on the ADAS-COG, it is estimated that between four and six patients taking donepezil 10 mg once daily for 6 months would need to be treated. Clinical experience in the UK suggests the NNT to achieve clinically significant activities of daily living score improvement is likely to be about twice that for the cognitive end point of ADAS-COG improvement of four points.

BRAIN AGEING: NEUROPROTECTION AND PREVENTION OF DEMENTIA

Neurochemical studies support an association between brain oxidative stress and AD[28,29]. Current studies are examining whether this association is a cause or a consequence of AD, perhaps an artifact of the AD process. Therapeutic agents are currently available (and more potent compounds are under investigation) that reduce oxidative stress. These agents may prove to be potent neuroprotective agents relevant to AD.

Evidence of oxidative stress in AD is detectable throughout the brain, irrespective of the site or extent of AD neuropathology. This evidence includes increased concentrations of advanced glycation end products[30], nitration[31], increased products of lipid peroxidation[32] and carbonyl modified proteins[33,34]. The sources of oxidative stress in AD extend beyond the generation of reactive oxygen species (ROS) during aerobic metabolism. Contributions are made by activated microglia near senile plaques[35] and by

interactions between the receptor for advance glycation end products and β-amyloid[36,37]. These observations have supported the hypothesis that the neurotoxic effects of β-amyloid are mediated through oxidative stress.

Therapeutic agents that reduce oxidative stress may reduce the incidence and slow AD progression. These include non-steroidal anti-inflammatory agents[38–43]; inhibitors of advanced glycation end product formation[44,45] and α-tocopherol[46]. The benefits in AD of *Ginkgo biloba* extract may also involve reduction of brain oxidative stress[47].

Neuroprotective actions of oestrogen in women were linked to reduced AD prevalence in some early studies[48] and prompted many subsequent observational and experimental longitudinal studies. As yet, no single study has overcome all the methodological problems associated with complex biopsychosocial questions of this type. A recent meta-analysis of 29 studies on the putative dementia-protective effects of oestrogen replacement therapy (HRT) suggested that HRT was linked with reduced risk of dementia (summary odds ratio, 0.66; confidence intervals 0.53–0.82). The authors cautioned that control for potential confounders may remove this association[49]. When demographic and health confounders were taken into account, HRT was not associated with cognitive benefits in a large ($n = 1907$) US study[50] of post-menopausal women. In the UK, the general practice research database identified women born before 1950, of whom 112 481 received HRT and 108 925 did not[51]. Among these subjects there were 59 newly diagnosed AD cases, of whom 15 (25%) were current HRT users. Expected HRT use was estimated at 24% and the authors concluded that this type of cross-sectional observation did not support a link between HRT and protection against AD.

Raloxifene is an oestrogen receptor modulator (mixed agonist/antagonist) that is tissue selective. Potential advantages are that it does not stimulate breast or uterine tissue but is active in bone and on lipid metabolism, the last being of specific relevance to the possible involvement of cholesterol in AD (see below). Osteoporotic postmenopausal women ($n = 7478$) were entered into a 3 year multicentre randomized placebo-controlled trial of raloxifene[52]. Mean cognitive scores were similar at baseline and there were no differences between groups over the study period. The authors concluded that, in osteoporotic women, raloxifene did not modify cognitive function over time.

As yet, it is unclear whether oestrogens are involved in AD. Although early observational studies were encouraging, recent large-scale and well-conducted studies do not provide cause for continuing optimism.

LESSONS FROM THE PREVENTION OF HEART DISEASE AND STROKE

Homocysteine and Vascular Disease

There is a rare autosomal recessive condition in which very high blood concentrations of total homocysteine are associated with increased incidence of occlusive vascular disease in adolescence—even in childhood[53]. This disease, homocysteinuria, is caused by one of several genetic defects in the enzymes that metabolize methionine; these defects occur in methylene tetrahydrofolate reductase (MTHFR) or cystathionine β-synthase (CBS). Premature vascular disease develops irrespective of the genetic defect and this indicates that homocysteine is probably responsible for the vascular damage[54,55]. Blood concentrations of homocysteine are also increased (but to a lesser extent) in individuals who are heterozygous for either of these two enzymes, MTHFR and CBS. Inadequate intake of folic acid and vitamins B_6 and B_{12} (co-factors in the metabolism of homocysteine) is also associated with increased blood concentrations of homocysteine[56–58]. Dietary supplementation using these vitamins is an important part of the treatment of genetically determined homocysteinuria. In the general ageing population, the contributions of genetic polymorphisms and nutritional intake to the determination of plasma homocysteine concentration (and in turn the risk of vascular disease) is largely unknown[59].

Epidemiological studies indicate that there is a strong positive association between blood homocysteine concentration and the risk of vascular disease. There is now considerable interest in the possible role of increased blood homocysteine concentration in brain ageing and cognitive decline leading to AD[60,61]. Nutritional factors are important in the maintenance of cognitive function in late life and specific dietary deficiencies may be relevant to the failure to retain mental abilities and progression to dementia[62–66]. Nutritional factors of most interest have been antioxidants, marine oils and fat-soluble vitamins. Maternal and infant nutrition is critical in neurodevelopment; folic acid is involved in the closure of the neural tube, and maternal folate deficiency during pregnancy is associated with neural tube defects. The maintenance of normal nervous system functioning in adulthood depends on an adequate consumption of B vitamins, including folate, B_6 and B_{12}. Acute deficiencies of these water-soluble vitamins are linked to neuropathy and psychosis. Age-related changes in metabolic and physiological systems may result in old people obtaining insufficient dietary folate and B_{12} or, to an uncertain extent, through mechanisms linked to atrophic gastritis, to failure to absorb these vitamins. In turn, insufficient intake can result in the accumulation of homocysteine[60], which is associated with greater unexpected cognitive decline and poor quality of life in old people[67] and in AD[68]. A recent review[60] commented on reports that low blood concentration of folate and B_{12} is associated with poor memory, impaired and non-verbal abstract thinking in old people. Low folate concentration is associated with poor spatial copying skills and, in very old age (90–101 years), lower blood folate concentration is linked to impaired encoding and retrieval.

The mechanisms by which homocysteine could impair mental function are uncertain. Homocysteine can undergo auto-oxidation to various metabolites and ROS (free radicals) that are directly toxic to the endothelium and also negatively alter the ability of vascular muscles to relax[69,72]. Homocysteine metabolites, such as homocysteic acid and cysteine sulphinic acid, act as endogenous agonists of NMDA receptors, over-stimulating glutamate receptors and ultimately inducing cytotoxic damage and brain cell death. Homocysteine is also associated with elevated cycline E (a marker of cell division) in the hippocampus of AD sufferers[68]. This raises the possibility that homocysteine may be involved in neuronal stimulation and trigger proliferative mechanisms, including the induction of new amyloid formation[69].

Currently, studies are under way to determine the cognitive effects in old people of strategies to reduce blood homocysteine concentrations, and early results are encouraging[70,71]. These strategies, if effective, may prove useful in community-based interventions to prevent cognitive decline and dementia in old people.

Cholesterol Metabolism and the Risk of Dementia

There is extensive evidence to support a link between lipid metabolism and dementia. Epidemiological evidence is as follows: (a) there is an established association between apolipoprotein E allele (APOEε4) polymorphism and AD; and (b) raised systolic blood pressure and high serum cholesterol in mid-life will increase the risk of AD in late life[73]; and (c) use of cholesterol-lowering agents (3-hydroxy-3-methylglutaryl co-enzyme A reductase inhibitors—the statins) is connected with reduced risk of dementia[74]. These findings were supported by Wolozin *et al.*[75] when they observed a lower prevalence of probable AD in subjects

prescribed two different statins (lovastatin and pravastatin). Laboratory evidence also supports an association between lipid metabolism and dementia. This includes decreased processing of amyloid precursor protein when cholesterol is removed from cell culture[6] and possible interactions between β-amyloid and low-density receptor-related protein in AD.

These observations have prompted renewed speculation along two separate lines. First, dietary manipulation of lipid metabolism may modify susceptibility to AD in subjects genetically predisposed to AD[77–81]. Second, randomized controlled trials that compare statins known to cross the blood–brain barrier with statins that do not will prove informative in the prevention of AD. Such studies are under way at several centres.

A substantial body of epidemiological data supports a proposed causal link between blood cholesterol concentrations and risk of coronary heart disease. The relationship is somewhat unusual, in that there is a steady increase of coronary heart disease risk from the lowest to the highest cholesterol concentrations observed in free-living communities. Some rural communities in China have mean cholesterol concentrations around 3 mmol/l and mean coronary heart disease death rates about 5% of those seen in England and Wales. This observation has prompted intensive strategies to lower cholesterol in the Western world to concentrations well below those typically aimed for. Individuals not previously considered to be hypercholesterolaemic now seek cholesterol-reducing regimes in order to reduce their perceived risk of myocardial infarction. It is as yet unknown whether these greater than previously sought-for reductions in cholesterol will be associated with reduced rates of coronary heart disease, as the epidemiological data suggest. Likewise, it is uncertain whether cholesterol-lowering regimes reduce the risk of cerebrovascular accidents. Nevertheless, these general principles in the modification of serum cholesterol concentrations in health and disease seem likely to inform the use of statins in the prevention and treatment of dementia[28].

FUTURE STRATEGIES

The cholinergic hypothesis provided a rational basis for drug development in AD[83]. Some symptomatic relief is consistently observed after the introduction of cholinesterase inhibitors, but subsequent attempts to improve modification of cholinergic transmission have not brought substantial improvements in rate or extent of response. There is, however, a reasonable expectation that longer-acting cholinesterase inhibitors with improved safety profiles will be available. The proposition that selective cholinergic neuronal death is a primary event in AD pathogenesis has prompted a search for therapeutic neurotrophic factors specific for cholinergic neurones.

Nerve growth factor (NGF) therapy is an example of this type of approach. It is based on extensive evidence that NGF is critical in the maturation and maintenance of cholinergic neurones and a possible modulatory role for NGF in amyloid precursor protein (APP) expression and secretion[84]. So far, problems of drug delivery have largely thwarted any chance of success. NGF shares these problems with other peptide drug delivery to brain sites. In summary, these are: (a) extra CNS peptide digestion; (b) failure to cross the blood–brain barrier and achieve therapeutic concentrations in the CNS; (c) inefficient distribution within the CNS; and (d) unwanted actions in CNS. The clinical pharmacology of neurotrophic factors is in its infancy and, once mature, seems likely to offer realistic prospects of contributing to AD treatment and prevention. Uses of neurotrophic mimetics (usually small synthetic molecules with growth factor-like activity) are likely to include the promotion of neuronal survival and differentiation after cell-based therapy[85–88]. Antisense strategies in AD therapy face similar problems. They possess considerable potential to target specific genes but so far none have been found useful in neurodegenerative disease[89].

Current drug development is based largely on better understanding of AD molecular pathology[90]. The "amyloid cascade hypothesis" of AD postulates that amyloid deposition is critical to the development of dementia and to neuronal death. Interventions are now proposed to prevent amyloid deposition and, when it occurs, to cause amyloid to disaggregate and be scavenged from the CNS[91,92]. Relatively little attention is paid to the development of therapies to prevent neurofibrillary tangle formation. A separate strand of research (described above) seeks to protect the brain against oxidative stress, inflammatory reactions, perturbations of calcium homeostasis, apoptosis and cerebrovascular endothelial function.

Figure 58a.1 shows key steps in the processing of APP. The deposition of extracellular amyloid is postulated to be the key event in AD pathogenesis. Three enzymes are involved; α-, β- and γ-secretases. The identification of these secretases raises the possibility that therapies aimed to modify their function could be useful in AD[93]. Several modulators of secretase function have been described, but so far none appear to have therapeutic applications[94].

The prevention of β-amyloid deposition may prove critical in AD treatment. Senile plaques contain not only β-amyloid deposits but copper and zinc that can be solubilized by Cu/Zn chelators *in vitro*. Recently researchers in Australia and Germany[95] successfully reduced β-amyloid accumulation in APP2576 transgenic mice (predisposed to β-amyloid deposition). This raises the possibility that therapies designed to remove brain Cu/Zn may be valuable in AD.

An alternative approach to β-amyloid deposition in AD is based on the production of antibodies to β-amyloid[96–99]. This technique seeks to dissolve senile plaques after they have formed and has the potential to prevent their formation. In studies of transgenic mice (TgCRND8 predisposed to β-amyloid accumulation), immunization with β-amyloid antibodies produced a marked (around 50%) reduction of β-amyloid in brain and was linked to reduced cognitive impairment[100]. More detailed behavioural studies were reported at about the same time[101]. These concluded that treated mice performed

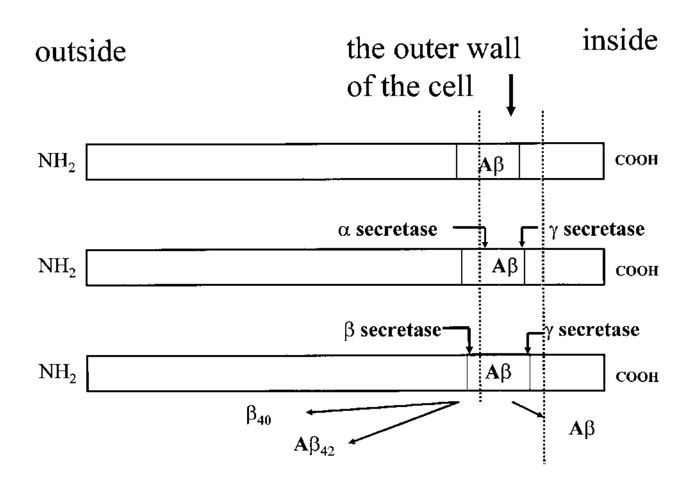

Figure 58a.1 Amyloid precursor protein (APP) is a transmembrane cellular adhesion molecule involved in synaptogenesis. It is processed by enzymatic cleavage to yield amyloid fragments (β_{50}, β_{42} and Aβ) of the original APP. Each cleavage enzyme acts at a specific point on APP. β- and γ-Secretases cleave at one or other end of the amyloid fragment. α-Secretase cleaves at a point between the two

"superbly" on the Morris water maze, whereas untreated mice did not. The authors remarked that their data did not support concerns that attempts to remove β-amyloid from brain might inadvertently cause wider dispersal and, therefore, more extensive β-amyloid neurotoxic damage. A later population-based observational study tested the hypothesis that the natural occurrence of antibodies to β-amyloid might reduce the incidence of dementia[102]. Although antibodies to β-amyloid could be detected, no reduction in AD was found.

CONCLUSION

The future for AD therapy holds much promise. As the general health of old people continues to improve and the incidence of functional disabilities is reduced, so the achievement of dementia prevention seems not only attainable but worthwhile. The huge collaborative international effort to understand the molecular pathology of AD and to design drugs to modify critical steps is certain to bring great benefit to those at risk of dementia.

Possible Future Treatments and Preventative Strategies for Alzheimer's Disease

Simon Lovestone
Institute of Psychiatry, London, UK

PREVENTION OR CURE?

It is a truism that prevention is better than cure, although historically both are usually preceded by palliation. Whilst this seems to be true also for Alzheimer's disease (AD), in that drugs for symptomatic treatment have preceded other approaches, the situation is complicated, both because these drugs may themselves alter the disease process and because prevention and cure (in the sense of reversing or modifying the disease pathogenesis) may be inseparable. The confusion largely results from the timing of the onset of AD. At the point of diagnosis, disease has already been established, probably for many decades. Careful pathological studies have demonstrated that a marker of neuronal damage in AD—highly phosphorylated tau—accumulates in neurons in certain cortical areas in mid-life and progresses to frank neurofibrillary tangle formation and neuronal death in these areas before the onset of clinical dementia[1]. Neuroimaging studies show that those with genetic risk factors for AD have evidence of functional damage decades before onset[2]. Truly preventative strategies, therefore, preventing even the onset of AD pathology, are probably not realistic. Rather, prevention will be secondary—preventing the disease process progressing to the point where it becomes clinically manifest. This approach (prevention) differs from approaches designed to slow the progression of disease once started (treatment) only in timing. It is best perhaps to think only of disease modification; either late, in which case it looks like slowing of disease, or early, in which case it looks like prevention. From the biological point of view, both are the same.

DISEASE MODIFICATION—DIRECTIONS FROM EPIDEMIOLOGY

Identification of risk factors for AD, such as vascular factors or diabetes, points the way towards obvious potential interventions to slow disease progression. It would be hoped that reducing hypertension and head injury, improving cardiovascular health and controlling diabetes well would all reduce the conversion of early pathology to clinical dementia. Time will tell whether this is the case. Worrying for this long-term strategy is the observation that treatment with insulin carries a higher risk than diabetes alone[3]. This may be a surrogate for disease severity but it does highlight that the route between epidemiology and public health may not always be obstacle-free.

Other population-based studies have suggested interventional possibilities for disease modification. Most promising at present is evidence suggesting that non-steroidal anti-inflammatory drugs may delay progression or prevent the appearance of symptoms[4]. Similarly, there is evidence linking oxidative damage to pathology and antioxidants to protection, and there may be an important role for vitamin E or some other antioxidant therapy in disease modification in the near to middle future[5]. The evidence linking hormone replacement and protection has a more limited potential, if only by virtue of gender. Studies are currently in progress that will determine whether any of these three approaches will have a clinical role in modifying the pathogenesis of AD.

DISEASE MODIFICATION—DIRECTIONS FROM MOLECULAR BIOLOGY

The advances in understanding the molecular biology of AD have been rapid and profound. It is clear already that this work will yield compounds designed to modify disease, although whether these compounds make the difficult passage between laboratory and clinic is a different matter. Preventing amyloid formation is the most obvious drug target and compounds designed to do this by inhibiting γ-secretase are in the late stages of development. Another, complementary approach is to increase the activity of α-secretase (thus hopefully reducing amyloidogenic metabolism). Interestingly, all cholinomimetic therapies should increase the activity of α-secretase indirectly, and this has been shown to be the case for M1 agonists[6].

The other pathology of AD, tangles, is a harder target as it is not yet clear why tau aggregates. However the importance of tau aggregation as a target is emphasized by the fact that this occurs in many neurodegenerative conditions[7], correlates with cognitive impairment and has functional consequences for neurons. Tau phosphorylation precedes aggregation and may cause aggregation in AD; certainly it inhibits tau function[8]. In neurons, tau is phosphorylated by an enzyme, glycogen synthase kinase-3β (GSK-3β), and inhibition of this would be expected to prevent tau phosphorylation[9]. Lithium inhibits GSK-3β and, as predicted, reduces tau phosphorylation[10,11]. Might lithium modify disease progression? Other GSK-3β inhibitors are in development. GSK-3β is also inhibited through the same signal transduction route as that induced by muscarinic agonists, and in line with this is the finding that muscarinic agonists reduce tau phosphorylation in cellular models[12]. It is possible that cholinomimetic therapies (including the cholinesterase inhibitors) will have some disease-modifying effect as well as a palliative effect[13].

Perhaps the most surprising and exciting development suggests that a vaccine is a therapeutic possibility for AD[14]. Amyloid peptide was used to inoculate transgenic animals overexpressing the amyloid precursor protein gene. In these animals, amyloid inoculation reduced amyloid deposition in the brain without any apparent adverse effects on the animals. It remains to be seen whether this is true in other animal models and whether cognitive deficits are also prevented. More importantly, it will be necessary to be very sure that there are no adverse consequences in man. The brain is supposedly (but probably not entirely) immunologically sacrosanct, and injecting a normal brain protein and stimulating an immune reaction has the very real potential of inducing auto-immune damage. Toxicity studies are under way that will address this concern.

TOWARDS DISEASE MODIFICATION —A TIME SCALE

The time scale of science is not linear; progress comes quicker these days and the only reliable prediction regarding the future is that predictions will continue to be usually wrong. However, disease-modifying treatments are already in clinical trials, and strategies such as HRT, anti-inflammatories and vitamin E are in use in other contexts. Another potential disease-modifying approach is to use the cholinergic therapies that are already in use for palliation. It should be known within the first few years of the new millennium whether any of these approaches have a true benefit for patients in modifying disease and, if so, given that experience in using these compounds in other contexts is extensive, then approval for use in secondary prevention may be rapid. Other approaches modifying amyloid and tau will take longer, not least because the time taken for novel drugs to travel from laboratory to clinic is best measured in decades.

Psychological and Psychosocial Interventions

Edgar Miller

Centre for Applied Psychology, University of Leicester, UK

Psychological interventions in dementia offer attempts to ameliorate the consequences of the disorder. They do not affect the underlying pathological process but are directed at helping those afflicted to function better and more independently. Interventions of this kind are based on the implicit assumption that those with dementia remain sensitive to environmental influences, even though the extent to which this is the case may be reduced. There is now good evidence that this assumption is justified[1,2].

GENERAL METHODS

Psychosocial interventions in dementia have been dominated by a number of approaches, which are designed to be generally applicable to all sufferers. These carry with them, whether explicitly or implicitly, the assumption that attention to a key impairment or principle is the key to effective intervention.

The assumption that an important feature of those with dementia is that they lose their orientation to time, place and person, lies behind reality orientation (RO), which is the earliest of these general methods[3]. There are two facets to RO. Firstly, regular group sessions, known as "classroom" or "group RO", involve sessions in which members may be led to recall the date and time of year, where they are, and so on. Secondly, "24-hour RO" may operate continuously and involves all who come into contact with sufferers, stressing information relating to orientation. An example of this is the nurse saying, "It is now 12 o'clock and time to take your tablets, Mrs Smith". This emphasizes information relating to time and person and links the time to the activity to be undertaken.

Evaluative studies have largely concentrated on group rather than 24 hour RO. In a review of these[4], it was concluded that sessions did lead to increases in verbal orientation (e.g. group members are more likely to be able to say what day it is). When it comes to changes in a wider range of cognitive functions or in behaviour, the evidence is very much less convincing.

Another general approach is that of reminiscence. This was originally proposed for normally functioning old people and is linked to the assumption that reminiscence and life review is a major task of old age. As used with those who suffer from dementia, it also builds on an area of relative strength, that of memory for the distant past. Group sessions are organized, with participants discussing how things used to be, usually with special materials such as photographs of the local city centre as it used to be 40–50 years ago. Reminiscence about how things were can be used as a basis for turning the discussion to how things are now.

Like RO, reminiscence has been popular, but relevant research has not offered strong support. The evidence that old people are especially prone to reminisce or that it necessarily leads to beneficial effects, such as increases in well-being or mood, has proved far from overwhelming[5]. Attempts to formally evaluate effectiveness in those with dementia have produced both negative findings[6] as well as some indications of modest benefit[7].

A more recent development of relevance to this section is what has become known as "dementia care mapping" (DCM), which is based on the writings of Tom Kitwood[8,9]. Kitwood stressed the "personhood" of people with dementia, and in his view the central aspect of personhood is found in social relationships with others. Good care is that which enhances personhood and well-being in terms of such things as enhancing self-esteem, enabling individuals to influence their own personal lives, promoting social confidence in terms of being at ease with others, and a sense of hope.

DCM is built more on a set of values than psychological principles, albeit values that almost no-one who is concerned for the welfare of these people would wish to dissent from, at least in general terms. What is lacking in this general approach is any detailed analysis of how these might best be turned into caring practices for elderly people with dementia, other than by feedback from an evaluative process, or "dementia care mapping" as more narrowly defined[10], to assess quality of care. This is based, firstly, on coding activities or inactivities according to whether they are expressions of "well-being" or "ill-being". Secondly, there is recording of episodes in which the person is demeaned or diminished. The obvious problems are those of reliably defining what is "well-being", "demeaning", etc., and no data as to the reliability of the method appear to be available.

This is just a selection of the general approaches or methods that are available and others are described elsewhere[1,2]. Most of these suffer from the limitation that, explicitly or implicitly, they see the problem of dementia as a single issue (e.g. loss of orientation in RO) or, as in the case of DCM, offer a set of very general values and principles. The best evidence as to effectiveness is still for RO, although even the positive impact of that is limited in extent. However, the search for better methods of care is not necessarily futile, since there is evidence that different forms of intervention, such as altering the layout of the furniture to make interaction easier, or enhanced activity programmes, can produce improvement[11,12].

SPECIFIC METHODS

As already indicated, approaches like those described in the previous section all assume a particular key factor, whether it be lack of orientation or the minimizing of personhood, offers the

key to optimal care. Against this is the argument that even such an ultimately devastating disorder as dementia does not obliterate all individuality and, in consequence, different people with dementia will have different problems and varied needs, even if there are some common elements. This does not deny that things like DCM and RO might have a general role, but it does mean there is also a need to consider individuals and their particular problems and circumstances.

A wide range of psychological interventions directed at specific problems, such as incontinence, memory failures and social behaviour, have now been described. These are based more in the kinds of psychological treatments developed for use with other clinical populations. Space does not permit an extensive description of these and more detailed information can be gained from other sources[1,2,13]. This section will merely offer a few illustrative examples.

Incontinence has always proved a difficult and almost intractable problem for psychological intervention. Nevertheless, some evidence of techniques able to produce beneficial effects has appeared. A system of checking for wetness and prompting going to the toilet has been found to produce positive effects, increasing the number of "dry checks"[14]. It is also interesting that one study has suggested that earlier failures to produce benefits with similar programmes might be at least partially attributable to staff failing to comply with the regime, rather than a failure of the method to provide positive effects when properly applied[15].

Aimless wandering can also be another feature that is difficult to manage. The adaptation of principles based on operant conditioning has shown some promise as a means to reduce this behaviour[16,17]. An interesting point in relation to this particular problem and, by implication, other problems as well, is that it is often unfortunately seen as secondary to intellectual loss and therefore only remediable if the primary problem can be tackled[13].

Finally, one possible way of ameliorating the problem of memory loss is to use external memory aids as prompts in order to lessen the load on the individual's own memory and to support retrieval. An encouraging account has described the use of this strategy with some success in the execution of daily living tasks, such as preparing a drink or snack[18].

COMMUNITY-BASED INTERVENTIONS

Most of the elderly population with dementia live in the community and are looked after by relatives, who can be under considerable strain[1]. Supporting carers therefore assumes considerable importance and extensions of the approaches described above have been made to deal with problems encountered in those resident in the community[13] (a wider discussion of community care issues is provided in Sections MI and MII).

One of the most obvious strategies is to provide support groups for carers, which may concentrate on providing information about dementia and discuss coping strategies, especially those used by group members. This strategy is described in greater detail elsewhere[1].

More formal methods, such as RO, have been adapted for use with community residents attending day hospitals. Similar effects to those obtained in applying RO in psychogeriatric wards and nursing homes were obtained. Again, the impact was most pronounced for orientation measures but with some effect on mood as well[19].

Finally, it is possible to use informal caregivers, such as spouses and children, as agents to implement more specific psychological interventions of the kind outlined in the immediately preceding section[20,21]. Problems tackled with some indication of success include the improvement of self-care skills and social interaction.

COMMENT

The most important conclusion that can be reached after surveying the evidence on psychological and psychosocial interventions for those with dementia is that people with even quite marked levels of dementia are responsive to psychological and environmental manipulation. This offers the essential foundation for the development of therapeutic or management strategies based on psychological principles.

Quite simple manoeuvres, such as rearranging chairs in groups to facilitate conversation, rather than leaving them in long regimented lines, can improve social interaction. Other relatively simple interventions can contribute to maintaining the basic skills associated with independent living. Despite being positively regarded by staff and patients, general methods like RO and reminiscence are of limited value and DCM remains to be evaluated. The best support is for RO, and indicates that small positive changes in orientation can be achieved. Since these methods are easy to apply, they can also be used as a general background on which more specific interventions can be built, and the successful addition of behavioural training to RO exploited in one investigation[22] can be seen as an example of this.

It may be that an important spin-off from general methods like RO is their popularity with direct care staff. Whilst this remains to be formally demonstrated, their use may help create and maintain a more optimistic and therapeutic attitude in staff, which can be a very worthwhile achievement in itself. In turn, this should make it easier to implement more specific interventions, more focused on individual needs.

As with psychological interventions in other contexts, the best results are likely to follow from the careful functional analysis of problem behaviour, whether this be a lack of behaviour or excessive and inappropriate behaviour, with specific interventions chosen in relation to the exact nature of the problem.

Overall, psychological and psychosocial interventions in the treatment and management of those with dementia are now capable of achieving modest but useful beneficial effects. They now must be regarded as a worthwhile part of any overall management strategy.

Informal Carers and Their Support

D. Buck
University of Liverpool, UK

This chapter is concerned with the need to support informal carers of people with dementia. It will describe how the importance of informal carers has been officially recognized in the UK, albeit partially. The shortcomings of state legislation are reflected in the narrow definitions of informal care that are still prevalent. Following a discussion of "What is caring?", this text will describe the significance of the role played by informal carers for both individuals with dementia and at the wider level. Then the chapter will explain how the rewards of providing informal care are often overshadowed by the adverse effects on carers' physical and emotional well-being. Some of the economic barriers faced by carers will also be outlined. Without adequate support, the ability of informal carers to maintain their role may diminish. A brief overview of the various interventions intended to "care for carers" will follow. It will be seen that many interventions are inadequate, and the need for proper evaluation will be highlighted. The chapter will end with a summary of the key messages.

POLICY BACKGROUND

In the UK the Carers (Recognition and Services) Act 1995 (1996)[1], gave some informal carers the right to ask for an assessment of their ability to care, and gave local authorities a duty to take into account the results of this when deciding what support to provide for the care recipient. However, carers can only have an assessment if they provide "regular and substantial" care and the person they care for is receiving an assessment. Thus, although the Act was a step forward, it should be extended if the true needs of dementia carers are to be met.

WHAT IS CARING?

Informal caring has been defined in many ways[2]. On the one hand, it is often defined solely in terms of the physical activities involved, e.g.:

> Anyone who looks after or cares for a handicapped person to any extent in their own home or elsewhere[3].

More recently, the Carers Act (1996)[1] promoted this view with its restriction to those providing "regular and substantial" care. In contrast, some argue that whilst "caregiving" is best thought of as the physical and behavioural activity of an informal supporter, "caring" can be seen as the emotional/affective element. Nolan *et al.*[2] provide a very useful definition, which will set the context for the remainder of this chapter:

> . . . caring comprises emotional, social and psychological aspects, as well as a general concern for others, in addition to practical tending.

THE IMPORTANCE OF THE INFORMAL CARER'S ROLE

The majority of caring is undertaken by relatives, and there are around 7 million informal carers of older or disabled relatives at home in the UK[4]. The extent and nature of the care provided is diverse, from continual to occasional help, and from assistance with personal care to the provision of a sympathetic ear. The number of people in England and Wales living with dementia is estimated to be around 550 000[5]. Although the number of people here caring for someone with dementia is not known, most people with dementia will have an informal carer. A study with which the author was involved[6] found that out of 502 mentally frail older people, 68% identified an informal carer. In the USA, Haley[7] found that 80% of the care of people with Alzheimer's disease in 1987 was provided by relatives.

Informal caring offers enormous benefit, both to the individual (carer and care recipient) and at a wider level. Tax-payers benefit in that institutionalization of the older person is prevented or delayed where there exists a willing and able informal carer. The Carers' National Association in the UK estimated that should just 10% of informal carers feel unable to continue their caring role, the cost of alternative care would be £2 billion/year[8]. On the individual level, many people in need of care prefer to receive it from their families, rather than formal carers[9]. However, this tendency is often dependent on the quality of the relationship[10]. The decision to choose formal care, on the other hand, is associated with a desire not to inconvenience or overload family and friends. Being able to provide care can be a fulfilling experience from the perspective of the carers, who often feel satisfaction at being able to improve the well-being and maintain the dignity of the older person, experience appreciation and companionship and feel they are reciprocating past help[6,11].

ADVERSE EFFECTS OF CARING

Despite the potential rewards of caring, many carers feel their own physical health, social and working life are adversely affected[6,8,12]. One survey of a district health authority in England found that 14% of its workforce were providing informal care for older people[13]. Many people who are working at the same time as caring for an older relative are eager to fulfil both responsibilities. But trying to balance competing demands is often problematic, with

many carers having to work fewer hours, take unpaid leave or stop working completely[14]. Thus, middle-aged carers may become disadvantaged, both in the short term in terms of loss of income, and in their later years because they have relinquished pension contributions.

Moreover, psychological distress is common among informal carers[7,15]. This is of wider concern, because psychological distress in carers is considered to be a predictor of breakdown of community care, i.e. of the older person's admission to long-term care[16,17]. The likelihood of poor psychological well-being (depression, anxiety, psychological stress) is greater in the carers of people with dementia compared with relatives of older people without dementia[12,18]. Vedhara *et al.*[19] found that stress levels were higher in carers of people with dementia than in a control group of similar socioeconomic status.

There are inconsistencies in longitudinal research of carers of people with dementia. Several studies found no significant deterioration in psychological well-being over time in carers of people with dementia[20–22], whereas other studies found significant changes[23,24]. It could be that depression levels are determined early in the caregiving career and remain stable for the duration of caregiving[21]. Although Wright[22] found no significant changes over time in depression, carers were significantly more depressed than non-carers by two year follow-up.

TYPES OF CARE

Bowers[25] proposed a useful typology of caring, beginning with anticipatory care, then preventive, supervisory and instrumental care. Central to all of these is the notion of protective care, whereby carers attempt to maintain the self-esteem and autonomy of the care recipient. In many cases this clashes with instrumental aspects of caregiving. Given that formal services often provide instrumental care, conflict may occur between service providers and carers[26].

CARING FOR CARERS

Much of the literature has called for assessment of the needs not only of older people but also of their informal carers. The UK Carers Act (1996)[1] has answered this call, up to a point. Ideally, interventions should be "facilitative" in nature[26], that is, systematic, planned in conjunction with the informal carer and care-recipient, and complementing the type of care that the carer already provides. Such interventions should be evaluated using sound methodological techniques, perhaps by a partnership of academic institutions and service providers. However, not all interventions are successful in alleviating carer stress, and some carers feel that interventions create rather than relieve the pressure (the place of informal carers in the therapeutic team is covered in Chapter 123 of this volume). Various types of assistance have been designed for informal carers. These include the provision of in-home or institutional respite services, support groups, skills training and education. Although carers value such interventions, they tend to be less effective than more intensive psychosocial interventions[7], such as counselling and psychotherapy. For a more detailed examination of a particular intervention for carers, readers may wish to refer to a special article in this book which outlines a training programme for carers of people with dementia in Sydney: *see* Chapter 138b.

Graham *et al.*[27] found that carers with greater knowledge of dementia were less likely to be depressed and more likely to perceive themselves as competent in their caregiving role. Buckwalter *et al.*[28] evaluated a psychoeducational nursing intervention for carers of people with dementia. In this individual-based intervention, carers learnt how to manage behavioural problems in the care recipient, and this resulted in decreased carer depression.

However, Knight *et al.*[29], in a review of interventions, concluded that while the effectiveness of respite and individual psychosocial interventions is moderate, such interventions with groups of carers are weak. This can be observed in a recent study that examined the effects of a group-based, dementia carer education programme[30]. This increased carers' knowledge of dementia, but there was no significant impact on their psychological well-being. The authors proposed that more intensive or individual interventions may be more successful. In another review of interventions, Melzer *et al.*[31] note that the optimum type of intervention (that is, individual vs. group) may vary, depending on the needs of the individual carer. Those requiring social support may benefit more from support groups, whereas those with psychological symptoms or problems with the caring role may benefit more from individual interventions. Furthermore, a brief intervention can be of short-term benefit but may dilute over time and become ineffective. McNally *et al.*[32], in their review of respite provision for carers, found little support for the existence of long-term benefits.

Zarit *et al.*[33] note that disappointing findings such as these may be due to methodological problems and/or the fact that services are provided at an inadequate level. Interventions are frequently optimistic and carers themselves not always as prepared to incorporate change as one might expect. Moreover, it is not always possible to balance the needs of carers with those of care recipients, or with cost issues, within one intervention. Thus, interventions should be facilitative in the way described by Nolan *et al.*[26]. They should incorporate the experiences of carers, and qualitative research methods ought to be used to elicit their concerns early on in the caring career. This could prove invaluable in determining the best way to help carers, whether that be to continue caring for their relative at home or in long-term care. Social changes, such as the size and structure of the family, and increasing geographical mobility amongst the workforce already pose a threat to the availability and willingness of informal carers. Failure to extend current legislation and provide the resources necessary to ensure adequate implementation, may well result in the further depletion of this pool of carers. Finally, some economic barriers to informal caring could be removed with the provision of full-time national insurance and pension contributions for carers.

SUMMARY

This chapter has discussed the importance of supporting informal carers of people with dementia. These carers represent the foundation of physical and emotional support for people with dementia, yet the rights and needs of carers themselves are not fully recognized. Supporting a relative with dementia can be a rewarding experience but many carers suffer adverse effects on their own physical and mental well-being. Not only that, but wider social and demographic changes may jeopardize the informal caring network as it currently exists. Should these "invisible" carers become unwilling, or unable, to sustain their caring role, then the consequences would be bleak, not only for people with dementia but also in terms of the costs of alternative care. On the other hand, some would question the view that such care should be left to those, usually female, family members who may otherwise have pursued a very different way of life. Whilst moves have been made officially to recognize the importance of the carers' role, there is still a long way to go before legislation will safeguard not only their needs but also their rights, including the right not to care. But if willing carers are to remain able carers,

then adequate and appropriate support for these individuals is crucial. The problem with this is that many interventions that are meant to support carers are inadequate or have been poorly evaluated. In particular, the effectiveness of group interventions is often weak compared with individual interventions, and there has been little evaluation of long-term benefits. Innovative approaches to caring for carers are needed, but at the same time barriers to implementation, such as lack of readiness in carers to embody change or inflexibility of the socioeconomic system, need to be removed.

The Role and Influence of the Alzheimer's Society

Nori Graham
Alzheimer's Disease International, London, UK

Over the last 20 years there has been a quantum leap in awareness of the fact that carers of people with dementia are among the most stressed and underprivileged members of the community. This has led carers to seek each other out, support one another and form self-help groups. Self-help groups form the backbone of national Alzheimer's societies, whose aim is to use professional means to improve the quality of life for people with dementia and their carers.

It is well recognized that carers have needs which, if met, can go some way to alleviate the stress. Alzheimer's societies can be a mechanism through which carers can articulate these needs and provide and give guidance to others.

The Alzheimer's Society in the UK arose from a small beginning in 1979 to one of the fastest growing and respected voluntary organizations in the UK, with a current income of £20 million. It has helped to raise public awareness about dementia amongst all sections of the population. Its success is due to its role in defining core services, a successful fund-raising strategy and the involvement of people with personal, business and professional experience. Its particular strength is that members all belong to one national society and are encouraged to meet locally in self-help groups and other activities. This has led to a branch structure, with local committees and paid workers supported by the national body.

Dissemination of information is the most important task for an Alzheimer's society. Answering enquiries and the availability of good professional material is a proven route to greater awareness and recognition.

Carers need services. These include domiciliary care, day care and residential care. With government grants a rarity and many societies operating on a shoe-string, there are insufficient or no services in most countries. Voluntary organizations, such as Alzheimer's societies, because of their great flexibility, are in a better position to be innovative than are statutory bodies. Alzheimer's societies can provide models of good practice and promote these vigorously as a basis for government action.

Building a strong national society takes a number of years. One has to decide on the aims, look at fund-raising opportunities, make financial plans, computerize the office, get together a good set of publications, put into place parliamentary lobbying, collect a good team of staff and volunteers and decide on a branch structure. Funding research is only possible for those larger societies with significant resources. All national societies face this array of tasks. The challenge for Alzheimer's Disease International, the umbrella organization of currently 60 national societies, is to support the very varied needs of national societies in different stages of development and with different cultural attitudes to older people and voluntary help.

Psychiatrists and other mental health professionals will find it well worth their while to become members of their national society and involved in its work. This increases the likelihood that governments worldwide will take seriously the impact of dementia on the individual and family, and provide resources to support people with dementia and their families.

The Psychiatric Manifestations of CNS Malignancies

M. Glantz and E. Massey
Duke University Medical Center, Durham, NC, USA

DIAGNOSIS

A variety of signs and symptoms may lead to the diagnosis of central nervous system (CNS) cancer. One-quarter to one-third of patients will be diagnosed following a recognized seizure[4,13,14,30]. Others will come to neurologic or neurosurgical attention because of focal weakness or headache[21,43,44]. Tumor-related alterations in behavior will be demonstrated by 50–90% of patients at some time during their illness[13,14,31–33], and in as many as two-thirds of all patients, a psychiatric manifestation is the initial or only complaint[31–39]. In a majority of these patients, the diagnosis of cancer is only made once "hard" neurologic deficits appear[14,24,26,36,39] or at autopsy[21,22]. Meanwhile, treatment for the psychiatric disturbance is often initiated. This pattern is most frequent in the elderly[22] in cases where the tumor occurs in a relatively "silent" area of the brain (the frontal lobe, occipital lobe, ventricle, corpus callosum or septum pellucidum)[37,40–46] and when the tumor is relatively slow-growing (astrocytoma, oligodendroglioma, meningioma)[11,14,31,32,34,37,43,45,47,48].

THE PSYCHIATRIC MANIFESTATIONS OF BRAIN TUMORS

Many factors, including the tumor itself, increased intracranial pressure[63], a variety of treatments, the patient's response to his illness and the premorbid personality, contribute to the psychiatric symptoms of patients with neoplasms (Table 60.1). These may be difficult to separate. Moreover, the signs and symptoms (both neurologic and behavioral) of a CNS cancer may be intermittent or may fluctuate[24,41,50,51]. Behavioral disturbances may resolve with surgery or radiation therapy, even if long-standing [39,45,48,51,52]. Frequently, they improve following ECT[55–57] or conventional pharmacotherapy—tricyclic antidepressants, selective seratonin re-uptake inhibitors or methylphenidate for depression[58]; lithium, haloperidol or carbamazepine for mania[31,32,59,60]; neuroleptics for schizophrenic symptoms[31,32,41]. Paradoxically, successful treatment of the psychiatric symptoms may delay the correct diagnosis if treatment is initiated without an appropriate search for underlying disease.

Table 60.1 Causes of neurobehavioral disturbance in patients with cancer

Direct involvement of the nervous system with cancer focal lesions
Increased intracranial pressure
Seizures
Metabolic derangements
Nutritional deficiencies
Endocrinologic dysfunction
Opportunistic infections
Complications of therapy
Psychological response to the illness
Neurologic paraneoplastic syndromes

Tumor-related Symptoms

Neurologic and psychiatric disturbances related directly to the presence of cancer in the CNS can be catalogued according to the type of symptom, or the site of the lesion (Tables 60.2 and 60.3).

Behavioral symptoms are most frequently reported (75–90% of cases) with frontal or temporal lobe tumors[33,47,61]. In about one-third of patients these are the initial manifestations

Table 60.2 Common neurologic deficits associated with focal brain lesions

Location of the lesion	Corresponding sign or symptom
Frontal lobe	Contralateral hemiparesis or hemisensory deficit; motor aphasia; Brun's ataxia; incontinence; frontal release signs (snout, grasp, etc)
Temporal lobe	Contralateral hemiparesis or hemisensory deficit; visual field abnormalities; aphasias
Parietal lobe	Contralateral neglect; visuospatial and cognitive disturbances; apraxia; contralateral visual field deficit
Occipital lobe	Contralateral visual field deficit
Basal ganglia, diencephalon, limbic structures	Contralateral hemiparesis or sensory disturbance; aphasias; visual field deficits; apraxia
Cerebellum	Limb (cerebellar hemisphere) or gait (midline) ataxia; dysarthria; eye movement disturbances
Spinal cord	Pain, weakness and sensory disturbance below the level of the lesion; sphincter dysfunction
Leptomeningeal	Cranial neuropathy; diminished (often asymmetric) deep tendon reflexes; weakness; radicular pain; sphincter dysfunction

Table 60.3 Focal central nervous system lesions associated with neuropsychiatric symptoms

Location of the lesion	Corresponding sign or symptom
Right hemisphere (especially temporal lobe and central lesions)	Delusions; schizophrenia-like behavior; mania
Temporal lobe Central lesions Parietal lobe (left) Occipital lobe (left)	Hallucinations
Frontal lobe Leptomeningeal Multifocal brain metastases	Delirium; encephalopathy; abulia
Temporal lobe Occipital lobe (right)	Anxiety; irritability
Frontal lobe Temporal lobe Central lesions Parietal lobe (left)	Depression
Frontal lobe Temporal lobe Central lesions Leptomeningeal Occipital lobe (left)	Memory impairment
Frontal lobe Temporal lobe	Euphoria; facetiousness

of the tumor. Distractibility, indifference, disinhibition, euphoria or mania[43,62], facetiousness, memory impairment[52,53,55], abulia, depression[31,43,45,54,64–67,73] and confusion are common in frontal lobe tumors[24,31,42,43,68,69]. Temporal lobe lesions can produce memory dysfunction (especially in the dominant hemisphere)[70–72], depression, and intellectual impairment[31,61,73,74]. Anxiety attacks, irritability, dissociative states, altered sexual behavior, mania (in right-sided or bilateral lesions)[32,60,62,75], and schizophrenic symptoms[24,35,46,76–79] have also been noted. The delusions which occur in this setting are usually paranoid in content and less complex in nature than those seen in true schizophrenia[80]. Non-epileptic visual and auditory hallucinations develop occasionally with frontal, temporal, parietal and occipital tumors, and probably represent "release" phenomena[82,83]. They are frequently prolonged, non-stereotyped and complex, in contrast to hallucinations produced by a seizure.

Tumors involving the limbic system, thalamus, basal ganglia, and diencephalon produce the next highest frequency of psychiatric symptoms[33,46,84–92]. Memory deficits[63], including Korsakoff's syndrome[90], depression[53], apathy and psychomotor slowing, have been described. Delusions, visual hallucinations, disinhibition, childish behavior, mania[59,75,91,93,94] and violent or emotional outbursts are also common[92].

A smaller number of patients (20–30%) with tumors confined to the parietal lobe develop psychiatric symptoms[33,61]. Intellectual impairment, depression and (with right-sided lesions) mania[34,44,60,95] are typical. Tumors of the occipital lobe are occasionally accompanied by behavioral symptoms[96], including memory impairment, irritability and visual hallucinations[82,96,97]. Behavioral disturbance is a relatively unusual finding in infratentorial tumors, although irritability, apathy, poor concentration and encephalopathy have all been reported[31,46,98] and a well-characterized "cognitive affective syndrome" can occur in the setting of cerebellar tumors or tumor surgery[99].

Leptomeningeal carcinomatosis is heralded by confusion, memory loss and cognitive impairment in at least 20% of patients, and mental symptoms ultimately develop in the majority of patients[14,17,100–102]. While myelopathy, radiculopathy and pain are the hallmarks of spinal cord and epidural tumors, psychiatric symptoms have also been reported[103].

Seizures

Seizures are the presenting sign of primary and metastatic brain tumors in one-quarter to one-third of patients, and occur in half of such patients at some point[14,30,104,105]. For patients with leptomeningeal disease, the corresponding frequencies are 6–7% and 14–26%[14,16,17,30]. Tumors located in the frontal and temporal lobes are most often associated with seizures; occipital lobe foci are uncommon; lesions in the basal ganglia, brainstem and cerebellum rarely if ever produce seizures[30,104,105]. Focal or generalized motor seizures are the most frequent and easily recognized seizure type; however, seizures may have solely behavioral manifestations[105]. Confusion may be the only observed manifestation of a seizure arising from any location. Visual and olfactory hallucinations may arise from frontal, temporal or occipital lobe foci. Memory lapses[106], feelings of anxiety or fearfulness[107], aggressive, inappropriate or psychotic behavior[108] and distortions of sound, space or size occur with temporal and frontal lobe seizures[109–113]. Rarely, the sensation of fear can be so overpowering that patients will run from a vaguely perceived threat ("cursive" epilepsy)[114]. Visual, auditory and olfactory hallucinations may be poorly formed (flashes of light, hissing or buzzing, unpleasant smells) or quite elaborate[115]. Patients may describe familiar (*déjà vu*) or unfamiliar (*jamais vu*) pictures or situations, snatches of music or overpowering (but inappropriate) feelings[112]. Disinhibition and feelings of compulsion[116] can occur with frontal lobe seizures. Schizophrenic[101,116] and manic–depressive symptoms[112–117] have been reported with temporal lobe foci in the dominant and non-dominant, hemispheres, respectively. Depression, weeping or laughter ("gelastic" epilepsy) also occur[114–118]. Although controversial, interictal behavioral abnormalities probably develop in a higher percentage of epileptic than non-epileptic patients[119–124].

Paraneoplastic Disorders

Psychiatric disturbances can also be produced by a number of indirect effects of cancer on the nervous system (Table 60.1). Of these, the neurologic paraneoplastic syndromes are the most difficult to diagnose[125–129]. These are seen much more frequently in the setting of systemic cancer than with primary brain tumors, and produce identifiable syndromes resulting in profound neurologic disability, in the absence of other causes. One type of "remote effect", paraneoplastic encephalomyelitis (PEM), frequently produces behavioral symptoms[129–132]. PEM is an inflammatory disorder of grey matter that may involve any level of the CNS, including the limbic system, cerebellum and spinal cord. With limbic encephalitis, the gradual (average 10.5 months) onset of anxiety, depression, hallucinations, bizarre behavior, paranoia and marked impairment of recent memory, progressing to dementia (the "Ophelia syndrome")[132], are characteristic. In one-third of cases, behavioral symptoms precede the diagnosis of cancer. Small cell carcinoma of the lung is the most common underlying malignancy, followed by breast, ovarian, gastric, testicular, uterine and non-small cell lung cancers and Hodgkin's disease. In addition to a characteristic clinical presentation and setting, well-defined serum antibody markers (Hu, Ma/Ta, CV2) are often present[133–135] and characteristic MRI findings have also been described[136,137].

Effects of Treatment

A final very important contributor to the psychiatric morbidity of patients with brain tumors is the effect of treatment[138]. Because patients are living longer and treatments are becoming more aggressive, the psychiatric complications of treatment have become common. While these "late effects" have traditionally been blamed on cranial irradiation, concurrent chemotherapy, corticosteroids and surgery are important contributors. The best-studied late effect is cerebral radionecrosis[139]. Typically, an enhancing mass develops at the site of previous cranial irradiation several months to several years after the completion of treatment. While headache, seizures and focal neurologic defects are often present, insidiously progressive personality change, abulia and lethargy may be the only early manifestations. A second late complication of cranial irradiation, also developing months to years after the completion of treatment, has been termed "radiation-related dementia"[40]. This is a more diffuse brain process, betokened radiographically by cortical atrophy, ventricular enlargement and increased white matter signal on T2-weighted and FLAIR MRI images. Again, gradually progressive cognitive impairment, abulia, short-term memory loss and personality change occur. Focal neurologic deficits are uncommon, although gait impairment and incontinence may develop. Frequently the correct diagnosis of a treatment-related complication is delayed while the diagnoses of depression, Alzheimer's disease, Parkinson's disease or normal pressure hydrocephalus are considered.

APPROACH TO THE PATIENT

The need for integration of psychiatric, neurologic and oncologic insights arises in at least three diagnostically different settings in patients with CNS cancer. In the most common scenario, a patient with known cancer or a proven primary brain tumor develops new or progressive psychiatric deficits. Frequently the symptom is iatrogenic, and withdrawal of the offending agent or substitution of some other therapy will be of benefit. Sometimes recurrent or progressive disease (a new metastasis, regrowth of a treated brain tumor) is the cause, and antineoplastic therapy is indicated. The new onset of seizures or a paraneoplastic disorder may be at fault, the symptom may have evolved from the patient's reaction to his illness. Recognition of these possibilities and an appropriately directed evaluation will often be of diagnostic and therapeutic value and will improve both the length and quality of life.

The patient with known psychiatric disease who develops new symptoms represents a second type of challenge. If focal neurologic deficits are prominent, a vigorous evaluation usually ensues. If the earliest or most obvious signs and symptoms are behavioral, a malignant etiology may be overlooked. Because psychiatric disease and cancer are both common, the chance development of cancer in a behaviorally abnormal patient will account for some of the apparent excess of brain tumors arising in patients in psychiatric hospitals. However, because behavioral changes are a common manifestation of CNS tumors and are especially easy to overlook in patients with chronic psychiatric illness, many cases elude early diagnosis. In patients with long-standing psychiatric illness, therefore, periodic evaluations should also include a detailed neurologic assessment.

A third diagnostically difficult situation occurs when an elderly patient presents with new psychiatric symptoms and no known cancer. Submitting all such patients to periodic neuroradiographic, electroencephalographic, neurologic and laboratory evaluations would eliminate most misdiagnoses, but is impractical and costly. Most secondary psychiatric disturbances in the elderly are due to toxic-metabolic, endocrine, cerebrovascular or infectious etiologies[41]. A detailed history supplemented by a few simple laboratory tests is usually adequate for diagnosis of these disorders. In most patients with CNS cancer, at least subtle neurologic abnormalities are demonstrable at the time of psychiatric presentation, although a careful neurologic examination may be required[47,52]. If not attributable to another known etiology (e.g. stroke, trauma, multiple sclerosis), such abnormalities should prompt additional studies. The presence of seizures, evidence of increased intracranial pressure (papilledema, headaches, nausea and vomiting), a disturbed level of consciousness, gradual intellectual decline, "frontal lobe" findings (also seen with temporal lobe and deep cortical lesions; Table 60.2), or persistent, unexplained headaches should also trigger further evaluation. In such patients, neuroimaging or examination of the cerebrospinal fluid (if leptomeningeal disease is suspected) is the best diagnostic approach.

Elderly patients with the new onset of psychoses, mania or hallucinations, suggestive family histories, normal neurologic examinations and no neurologically worrisome complaints rarely harbor CNS malignancies. Nevertheless, the number of these "idiopathic" cases, after toxic and metabolic etiologies have been excluded, will be so few and so unusual that neuroimaging is probably justified. In contrast, depression is common in the elderly. A careful history and examination are obligatory.

Peripheral Neuropathy and Peripheral Nerve Lesions

Janice M. Massey and E. Wayne Massey
Duke University Medical Center, Durham, NC, USA

Peripheral neuropathy is a diffuse process involving either sensory nerves, motor nerves or, more frequently, both. It is the most common neurologic disease of the elderly. The known causes of polyneuropathy are numerous and are frequently associated with other systemic illness (Table 61.1). Many occur in patients with psychiatric symptoms. Additionally, drugs must always be considered as possible etiologies.

In addition to diffuse peripheral neuropathy, the pattern of single peripheral nerve involvement is termed mononeuropathy. The causes include acute trauma or entrapment but often are non-traumatic in origin, presumably representing either chronic trauma or due to other factors, such as infarction of the nerve (diabetes mellitus or collagen vascular disease). Patients with many psychiatric diseases are more prone to these problems, i.e. peroneal or ulnar pressure palsies in depressed patients.

POLYNEUROPATHY

Symptoms of diffuse peripheral neuropathy include a ''stocking glove'' distribution of sensory loss usually involving the feet and later the hands. With sensory involvement, patients complain of numbness and tingling or pain in the feet. Early on, the hands are rarely involved to any significant degree. On examination, varying degrees of decreased perception to pain, temperature or vibratory sense and, less often, joint position sense may be seen in the distal extremities, particularly in the feet. When this sensory loss is severe in the lower extremities, there may be unsteadiness of gait, worse with the eyes closed.

When the motor nerves are involved, distal muscles of the feet and hands may be weak. The patient may walk with a ''foot drop'' or be unable to stand on tiptoe due to distal lower extremity weakness. Intrinsic hand muscle weakness produces decreased hand grip. Reflexes are hypoactive, initially at the ankles, but may subsequently be absent at the knees and even in the upper extremities. All symptoms and signs, including the reflexes, are usually symmetrical.

The temporal profile of the symptoms may suggest possible etiologies. Neuropathy of sudden onset is seen in inflammatory or vasculitic disease, whereas patients with familial history and long-standing neuropathy are more likely to have hereditary disease.

We will discuss only the most common diffuse neuropathies.

Landry–Guillain–Barré–Strohl Syndrome (AIDP)

Immune polyradiculoneuropathy (polyradiculoneuropathy, Guillain–Barré syndrome) may be preceded by a minor febrile illness or following immunization. Symmetrical motor weakness, often beginning in the legs and ascending, and areflexia with minimal sensory involvement, are the primary features. The cerebrospinal fluid (CSF) protein is usually increased and no cells are present. This relationship is termed cytoalbuminologic dissociation. Facial diplegia without extra-ocular muscle or pupillary involvement may occur. Respiratory weakness may develop rapidly. The severity of the illness ranges from minimal weakness to flaccid quadriparesis. Although usually idiopathic, known causes include AIDS, rabies, cytomegalic and other viruses. Porphyria may cause neuropathy along with psychiatric symptoms.

Quadriparesis may develop rapidly, requiring respiratory support within an hour. Usually the symptoms progress over 3–4 days, although occasionally it may take weeks to develop the maximum deficit. Spontaneous recovery, usually complete, occurs over weeks or months as a rule. However, some patients have serious residual deficits.

Respiratory function may deteriorate rapidly, even without obvious respiratory distress. When Guillain–Barré syndrome is suspected, serial pulmonary functions should be performed. When the forced vital capacity drops below 1–1.5 L, intubation is indicated. Autonomic dysfunction is common, with symptoms ranging from bladder dysfunction and labile blood pressures to cardiac rhythm disturbances.

Therapy is supportive. Maintenance of adequate respiration and nutrition, treatment of infection and autonomic disturbances, good nursing care and physical therapy to prevent contractures are required. Plasmapheresis, immunoglobulin therapy (IgG) and, less often, steroid therapy may shorten the course of the illness.

A chronic relapsing form of inflammatory demyelinating neuropathy (CIDP) is an increasingly important neuropathy and often responds to corticosteroid treatment. Nerve biopsy is occasionally helpful to confirm the diagnosis.

Diabetic Neuropathy

Various portions of the peripheral nervous system can be affected by diabetes mellitus. Diabetes is common in the elderly. Individuals with psychiatric disease will frequently have diabetes with neuropathy concomitantly. The most frequent pattern is a distal symmetric predominantly sensory polyneuropathy. Painful

Table 61.1 Peripheral neuropathy: etiology and classification

1. Neuropathy associated with toxic metabolic states
   A. Vitamin deficiency (B_1, B_{12}, B_6, nicotinic acid, pantothenic acid and folic acid)
   B. Diabetic
   C. Uremic
   D. Hepatic
   E. Thyroid disease
   F. Dysproteinemias and paraproteinemias
   G. Alcohol
   H. Amyloid
2. Inherited peripheral neuropathy
   A. Charcot–Marie–Tooth
   B. Dejerine–Sottas (hypertrophic)
   C. Roussy–Lévy
   D. Refsum's disease
   E. Tangier disease and Aβ-lipoproteinemia (Bassen–Kornzweig's)
   F. Neuropathy associated with the leukodystrophies (metachromatic leukodystrophy, Krabbe's disease, adrenoleukodystrophy)
   G. Fabry's disease
   H. Porphyric neuropathy
   I. Friedreich's disease
   J. Tomaculous neuropathy
3. Infectious, inflammatory and post-infectious neuropathy
   A. Guillain–Barré syndrome, inflammatory polyradiculoneuropathy
   B. Diphtheria
   C. Leprosy
   D. Sarcoid
   E. CIDP (chronic inflammatory)
   F. AIDS
   G. *Campylobacter*
4. Neuropathies associated with malignancy
   A. Neuropathy associated with lymphoma and Hodgkin's disease (sensory, motor, mixed)
5. Toxic neuropathies
   A. Heavy metals
      1. Lead
      2. Arsenic
      3. Mercury
      4. Thallium
   B. Toxins
      1. Acrylamide
      2. Trichloroethylene
      3. Benzene
      4. Carbon tetrachloride
      5. TOCP (triorthocresyl phosphate)
   C. Drugs
      1. Vincristine, vinblastine
      2. Chloroquine
      3. Nitrofurantoin
      4. Phenytoin
      5. Disulfiram
      6. Isoniazid
      7. Thalidomide
      8. Excessive B_6 administration
      9. Dapsone
      10. Amioderone
      11. *cis*-platin

burning or numbness and tingling in the toes and feet, and less commonly the hands, are present. Often a "stocking glove" distribution of decreased pain, temperature and vibration perception is present, along with decreased distal reflexes.

Patients with longstanding diabetes or poor glucose control usually have more severe neuropathy, although these do not always correlate well. In addition, mononeuropathy (involvement of single motor or sensory nerves) is frequently seen in diabetes. Femoral neuropathy produces pain in the anterior medial thigh, with weakness in the proximal muscles of the leg. Lumbosacral plexus involvement with weakness and atrophy of the thigh muscles is termed diabetic amyotrophy. Mononeuritis multiplex involves multiple sensory and motor nerves in an asymmetrical fashion, usually due to infarction of the nerves. However, multiple mononeuropathies may also occur, due to pressure or entrapment. These need recognition so that patients can be taught how to prevent further trauma or compression of their nerve. Radiculopathy in the thoracic or lumbar area without disc herniation also occurs frequently in diabetes. In the thoracic area, patients complain of chest wall or abdominal pain, usually unilaterally, and may have abdominal musculature weakness. The autonomic nervous system may also be involved, causing orthostatic hypotension, bladder and gastrointestinal disturbances, skin changes, sweating abnormalities and impotence. A penile prosthesis may be helpful in male patients with impotence.

Alcoholic Neuropathy (Nutritional/Toxic)

This neuropathy is most often sensory, with pain on the soles of the feet and loss of ankle reflexes. Minor motor involvement may occur, but is seldom severe. This is associated with vitamin B_1 deficiency, but is also likely a direct toxic effect from chronic alcohol use. A history of the amount and frequency of alcohol intake is essential in evaluating these problems. Abstinence from alcohol is necessary to result in any improvement. Psychiatric care is usually the predominant need in these patients, however.

Evaluation of Patients with Neuropathy

Evaluation for systemic disease in patients with peripheral neuropathy must include several factors: patient history, physical examination, basic laboratory studies and special laboratory analysis.

The history should include a detailed family history, but this may be difficult to obtain. Sometimes additional family members must also be examined. The social history should include occupation, types of hobbies and possible exposure to toxins. Other medical illness should be noted. A complete record of all drugs used, including prescription, non-prescription and recreational drugs, should be obtained. One should determine whether onset of symptoms correlates with initiation of a drug regimen. Recent medical history should include risk factors for possible infectious etiologies, such as tick exposure, high-risk sexual

Table 61.2 Approach to history in peripheral neuropathy

Family history: diabetes mellitus, pernicious anemia, amyloidosis, porphyria, Refsum's disease, Tangier disease

Social history: alcoholism, occupation or hobbies with possible toxic exposure (carbon tetrachloride, carbon disulfide, carbon monoxide, trichloroethylene, trinitrotoluene, benzene, *o*-dinitrophenol, lead, arsenic, bismuth, mercury, thallium, copper, silver, gold, antimony, zinc), intentional poisoning (suicide, homicide), heavy smoking (carcinoma of lung)

Medication history: sulphonamides, emetine, hydralazine, nitrofurantoin, diphenylhydantoin, glutethimide, isoniazid, allopurinol, thalidomide, insulin

Recent medical history: infections (AIDS, diphtheria, tuberculosis, infectious mononucleosis, infectious hepatitis, syphilis, typhoid, typhus, "strep throat", cat-scratch fever), malignancy (direct invasion or remote effects), gastrointestinal disturbances (seen with arsenic, lead, porphyria, thallium, vitamin deficiencies, pernicious anemia, hepatitis, Tangier disease)

Table 61.3 Physical examination in peripheral neuropathy

Hair: alopecia (thallium, arsenic), premature graying (pernicious anemia)
Skin: dry skin (myxedema), dermatitis of exposed surfaces (pellagra, porphyria), erythematous sweaty palms (alcohol, arsenic), depigmented areas (leprosy), ecchymoses (blood dyscrasias, hypercortisonism), butterfly rash or poikiloderma (lupus), ichthyosis (Refsum's disease)
Nails: Aldrich–Mees lines (arsenic), petechiae under nails (subacute bacterial endocarditis)
Gums: lead line (lead), gingival hyperplasia (diphenylhydantoin)
Tongue: glossitis (pernicious anemia, pellagra), large tongue (acromegaly, amyloid)
Sore throat: infectious mononucleosis, diphtheria, leukemia
Salivary glands: enlargement (sarcoid)
Eyes: third-nerve palsy without pupillary involvement (diabetes)
Fundi: Roth's spots (subacute bacterial endocarditis, blood dyscrasia), hypertensive changes (uremia, periarteritis), dilated veins (macroglobulinemia), retinitis pigmentosa (Refsum's disease)
Adenopathy: infection, malignancy, sarcoid
Cardiac enlargement: myxedema, beri beri
Hypertension: periarteritis, porphyria, thallium
New heart murmurs: subacute bacterial endocarditis
Hepatomegaly: alcoholism, malignancy, hepatitis
Ankle edema: uremia, beri beri, malignancy of kidney (especially if unilateral)
Wristdrop: lead
Slow relaxation of deep tendon reflexes: myxedema
Joint deformities: rheumatoid arthritis with or without vasculitis, gout
Reddish brown urine: porphyria

Table 61.4 Initial laboratory studies in evaluation of peripheral neuropathy

Urinalysis: chronic nephritis, hematuria (malignancy, proteinuria, myeloma)
Erythrocyte blood count and hemoglobin: anemia (infection, malignancy), macrocytic anemia (pernicious anemia, diphenylhydantoin), basophilic stippling (lead), acanthocytosis on fresh smear
Blood smear, fresh: acanthocytosis
Leukocytes: depressed count (lupus, toxicity), increased count (periarteritis, infection), hypersegmented neutrophilis (pernicious anemia), abnormal leukocytes (leukemia, malignancy, toxicity, infectious mononucleosis)
Sedimentation rate: elevated in collagen disease, infection, malignancy, cirrhosis
Chest X-ray: carcinoma of lung, sarcoidosis infection, enlarged heart (myxedema, beri beri, hypertension)
Serum creatinine: uremia (including lupus)
Fasting blood sugar (glucose tolerance test): diabetes mellitus
Thyroid panel: myxedema
Serum cholesterol: decreased in thyrotoxicosis and Tangier disease, increased in myxedema

Table 61.5. Additional laboratory studies (if clinically indicated)

Genetic studies: (GM1, H5MN)
Antibodies: (anti-maG, anti-Hu)
HTLV I, HIV (serum)
Hair and nail analysis: arsenic
Urine: heavy metals, porphyrins
Liver function studies: hepatitis, alcholism
Schilling's test: pernicious anemia
Cultures: infection
Serum uric acid: gout
Rheumatoid factor
Lupus erythematosus preparation (FANA)
Heterophil antibody titer
Biopsy of nodes, liver, kidney, testicle (periarteritis): malignancy, sarcoid, lupus, cirrhosis
Rectal biopsy: amyloid, Tangier disease
Nerve biopsy: vasculitis, amyloidosis, leprosy, sarcoidosis, embolic disease, Refsum's disease

Table 61.6 Genetic (DNA) tests in peripheral neuropathy

1. Hereditary
   CMT1 Evaluation (DNA) CMT 1A, 1B, 1X
   Peripheral myelin protein 22 (PMP22)
   Early growth response 2 gene (EGR2)
   Axonal HMSN, Dejerine–Sottas, congenital hypomyelination, HNPP, Refsum's
   TTR 30 Amyloidosis DNA Test
2. Acquired peripheral neuropathy:
   MAG, GM1 Triad, Sulfatide, Galop,
   Hu, MAG "Dual" Antigen
   Autoantibodies for GM1, MAG, GQ16,
   Sulfatide, Galop

activity or blood product exposure, and include a detailed review of systems (Table 61.2).

In addition to the neurologic examination, one should include attention to the general examination for evidence of systemic illness that could cause the underlying neuropathy (Table 61.3). Initial studies in the evaluation of peripheral neuropathy include many routine laboratory tests (Table 61.4). Specific laboratory studies are also useful. Nerve conduction studies reveal diffuse abnormalities in the motor and sensory nerves in patients with diffuse neuropathy. Electromyography is abnormal if axonal damage has occurred. These tests characterize the neuropathy as primarily demyelinating or axonal and recognize unusual patterns of response. Specific patterns are useful in establishing an etiology[2].

Genetic studies, analysis of hair, nails, and urine for heavy metals, liver function studies, Schilling's test, cultures, fluorescent antinuclear antibody (FANA), sedimentation rate, rheumatoid factor, evaluation for malignancy and possibly nerve biopsy, may be required in specific cases (Tables 61.5 and 61.6).

COMMON MONONEUROPATHIES

The most common mononeuropathies include involvement of the median, ulnar and radial nerves in the upper extremity and femoral, peroneal, lateral femoral cutaneous and sciatic nerves in the lower extremity. In addition, truncal neuropathies and even cranial nerve involvement may cause a localized sensory or motor deficit (Table 61.7).

Table 61.7. Common mononeuropathies

Cranial mononeuropathy
   VII Facial (Bell's palsy)
   V Trigeminal (mental nerve)
   IV, VI, II, III
Extremity mononeuropathies
   Median
   Ulnar
   Radial
   Brachial plexus
   Lateral femoral cutaneous (meralgia paresthetica)
Femoral
Peroneal
Obturator
Sciatic
Truncal neuropathy
   Intercostal (*Herpes zoster* and diabetic)
   Posterior primary rami T2–T6 (notalgia paresthetica)

Knowledge of the symptoms, signs and anatomic distribution of specific peripheral nerves is essential to recognize and diagnose the mononeuropathies. These mononeuropathies are common in the elderly. The most common chronic mononeuropathy is carpal tunnel syndrome (CTS), entrapment of the median nerve as it passes under the carpal ligament at the wrist.

Entrapment injury to the ulnar nerve is common in chronic illness, particularly in the elderly population. Psychiatric patients restricted to bed or a wheel chair use their elbows for support and often compress the ulnar nerve at the olecranon notch, producing a "tardy ulnar palsy". The supine position, with the arms in a position of mild flexion with the forearm pronated, exposes the ulnar nerve to chronic pressure.

The radial nerve innervates the extensor muscles for the fingers, wrist and elbow. The most common site of injury of the radial nerve is in the proximal portion of the nerve as it wraps around the humerus. Injury often occurs when the patient is deeply asleep or unconscious (usually due to alcohol or sedation) while the arm is held in abduction and lateral rotation. Injury results when the nerve is compressed by the head of a sleeping partner lying against the humerus ("honeymoon palsy"); or falling asleep with the arm propped over a bench, chair or bar ("Saturday night palsy").

The lateral femoral cutaneous nerve, a sensory nerve that arises from the lumbar plexus, is often entrapped at the medial border of the anterior superior iliac crest, producing an acute or subacute onset of numbness and a disagreeable prickly sensation over the lateral thigh (meralgia paresthetica). Sigmund Freud was one of three early describers of this and experienced it himself. Recognition is important, if only to avoid intervention to treat other conditions, such as lumbar radiculopathy.

Peroneal nerve injury produces footdrop or loss of sensation in the anterolateral surface of the foot. This can be subtle. The most common cause of common peroneal nerve injury is crossing the legs. Immobility is a predisposing cause, and depression, stroke or dementia is present among many patients.

Sciatica is usually caused by a protruded lumbar disc affecting the S1 root. However, the sciatic nerve is susceptible to injury at various sites in the buttocks causing identical symptoms and signs.

Idiopathic inflammation of the brachial plexus (neuralgic amyotrophy, cryptogenic brachial plexopathy, Parsonage–Turner) predominantly affects the superior trunk of the brachial plexus. A deep aching pain in the axilla or shoulder is followed within a few days by weakness of muscles supplied by the superior brachial trunk.

Electroencephalography (EEG)

The Late George W. Fenton
University of Dundee, Scotland, UK

It is 60 years since Berger[1] demonstrated electroencephalographic abnormalities in an histologically confirmed case of Alzheimer's disease. Since then, the electroencephalograph (EEG) has been widely used in the investigation of patients with suspected organic brain disease. To interpret the results in an individual patient, a number of observations relating to the nature and origin of the EEG signal and the impact of healthy ageing on its waveforms must be considered.

PRINCIPLES OF EEG INTERPRETATION

The EEG samples the electrical activity of the cerebral cortex only. Further, widespread synchronous involvement ($6\,cm^2$ or more) of the cortex is required to significantly alter the scalp EEG waveforms. Cerebral neuronal dysfunction caused by different disease processes produces essentially similar patterns of EEG disturbance. Hence, with a few exceptions, the type of EEG change cannot predict the precise nature of the underlying pathology. Finally, acute cerebral disease or rapidly deteriorating dysfunction cause the most florid electrical disturbance, while static lesions produce little or none, unless epileptogenic activity develops with the generation of spikes, sharp waves, spike–wave complexes, etc.[2]

EFFECTS ON HEALTHY AGEING

The more important changes that accompany healthy ageing include alpha rhythm frequency slowing, changes in beta (fast) rhythm abundance, the appearance of diffuse delta activity, local anterior temporal delta wave foci and alterations in nocturnal sleep patterns[3,4].

Mean Alpha Rhythm Frequency

In young adults, this is around 10 Hz and does not change until 60 years. Subsequently there is a gradual decline, the rate of decrement varying from 0.05 to 0.75 Hz/decade across studies; 9.0–9.5 Hz at 70 and 8.5–9.0 Hz after 80 years. Indeed, in healthy subjects of any age it is rare to have a dominant (alpha) rhythm frequency of less than 8 Hz. In elderly patients, the degree of alpha frequency slowing is significantly related to the extent of cognitive impairment.

Low-voltage Beta (Fast) Activity

This is a low voltage 15–30 Hz rhythm, arising from the frontocentral areas of both hemispheres and sometimes diffuse in distribution, which increases in abundance in middle age and is more prominent in females. It persists into old age but diminishes markedly after 80 years.

Diffuse Slow Activity

This consists of background theta (4–7 Hz) and delta (1–3 Hz) waves of generalized distribution, is not seen in healthy people under 65 years and is relatively rare in early senescence (7% of people under 75 years), but occurs in up to 20% of persons over 75 years. Even in this relatively aged population the degree of diffuse slowing is mild. When moderate or severe, there is a significant association with a clinical diagnosis of dementia.

Focal Delta Waves

A substantial minority (30–40%) of healthy people over 60 years have focal delta (slow) waves strictly localized to the anterior temporal region and often lateralized to the left side. More extensive spread beyond the anterior temporal area indicates local pathology.

Paroxysmal Activity

Paroxysmal EEG events are transient, higher voltage waveforms that arise suddenly from the EEG background. The healthy brain generates some normal paroxysmal activity, namely lambda waves during wakefulness when the eyes are open and paroxysmal waveforms during sleep as part of the alerting process (lambdoid waves in light sleep and K-complexes in medium to deep sleep). Abnormal paroxysmal discharges include bifrontal delta wave episodes, spikes, and sharp waves and spike–wave complexes. Such phenomena are extremely rare in healthy elderly people.

Nocturnal Sleep Patterns

EEG sleep studies of healthy elderly individuals show decreases in sleep efficiency, greater numbers of awakenings from sleep with increases in total time awake (especially in the last 2 h of the night) as well as marked diminution in stages 3 and 4 sleep. These

changes, which usually begin somewhere around 50 years of age, are age-related and generally more pronounced in men[5]. A shortened rapid eye movement (REM) latency may be helpful in separating early dementia (normal REM latency) from depression (shortened REM latency). The former show decreased amounts of sleep spindles and K-complexes with reduced REM sleep percentage and a normal REM temporal distribution.

EEG IN DEMENTIA

With important exceptions, the changes in dementia are qualitatively similar to those of healthy ageing, although the degree of change is much more marked. Since the days of Berger, there have been many studies of the routine clinical EEG in dementia (reviewed by Busse[6], Pedley and Miller[7], Fenton[4]).

Changes Common to Most Dementing Disorders

Slowing of the dominant, parieto-occipital (alpha 8–13 Hz) rhythm over both hemispheres, a moderate to marked increase in generalized theta (4–7 Hz) and delta (1–3 Hz) activity (diffuse slowing) and a bilaterally symmetrical decline in low voltage beta (fast) activity are common background activity changes. One autopsy study reports a significant correlation between alpha frequency slowing and the number of senile plaques counted in Alzheimer's disease (AD) patients' brains[8]. Paroxysmal runs of bifrontal delta activity are not uncommon in dementia patients. In one investigation these have been related to degenerative brain stem changes at autopsy[9]. The occipital responses to photic stimulation at fast flicker rates (equal to or greater than 18 flashes/s) tend to disappear in a significant minority of dementia patients (1 in 5).

Differences Between the Various Dementias

AD vs. Pick's Disease

Studies that have compared the various types of dementing illnesses indicate that less than 5% of patients with histologically confirmed AD have a normal EEG even when first referred to the psychiatric services[4,10–12]. In contrast, Pick's disease and multi-infarct dementia (MID) are not infrequently associated with normal EEGs. The number of Pick's disease patients in any study is small, but a consistent finding is that around 50% have normal records. Even when diffuse slowing is present in Pick's disease patients, the alpha rhythm is better preserved[9,12,13]. The alpha rhythm is generated by the parieto-occipital areas of the cerebral cortex modulated by thalamocortical influences. The histological changes in Pick's disease are largely confined to the frontotemporal regions, which are relatively "silent" electrically, compared to the parieto-occipital areas, where the predominant AD changes occur. Indeed, it has been recently suggested that a normal EEG is one of the characteristic features of dementia of frontal lobe type: a dementing syndrome with onset in the presenium and selective frontal lobe dysfunction. It is not clear whether it represents a form of Pick's disease[14].

Multi-infarct Dementia (MID)

The EEG in MID differs from AD in displaying significantly more asymmetry between the hemispheres, localized slow wave disturbances being particularly common, while the alpha tends to be better preserved. For example, Constantinidis *et al.*[15] report three times more alpha rhythm and five times more local slow wave foci in MID. Often, the laterality of the EEG focus in MID correlates with past or present clinical evidence of an ischaemic lesion lateralized to the same side. In contrast, AD patients have a significantly higher incidence of diffuse delta activity.

Huntington's Disease

The EEG in Huntington's disease differs from the dementias already discussed. In a variable number (30–80%) depending on the series reported, a low voltage tracing with an average amplitude of 10 μV or less is a characteristic feature. This amplitude reduction correlates with caudate nucleus involvement but only becomes apparent by the time the disease is clinically well-established[16,17].

The Significance of Paroxysmal Abnormalities with Periodocity

Paroxysmal bifrontal runs of delta waves are common in dementia patients, especially those with AD. In one histological investigation, this bifrontal delta activity has been related to degenerative brain stem changes[9]. Regularly recurring (periodic) generalized biphasic or triphasic sharp wave or slow wave complexes of generalized origin with a characteristic recurrence rate of 0.5–1.0 s (intervals between successive bursts of complexes) are a characteristic feature of Creutzfeldt–Jakob disease (CJD). Early in the illness, diffuse background slowing occurs and in most cases the characteristic periodic complexes emerge. In a minority of patients (up to one-third in some series), especially the amyotrophic cases, this pattern may not be seen or may appear late. If practical, serial recordings are recommended[18]. On rare occasions, the periodic discharges may be temporarily focal, later generalizing and becoming bilaterally synchronous as the disease progresses. Their presence in a middle-aged or elderly patient with dementia is highly suggestive of CJD. Periodic triphasic waves of generalized distribution can be seen in other conditions, notably hepatic and other metabolic encephalopathies, subacute sclerosing leucoencephalitis and Unverricht's myoclonus epilepsy. Rarely they may appear in advanced AD patients and in Binswanger subcortical encephalopathy but do not show the characteristic periodicity or evolution of CJD.

EEG, COGNITIVE AND CT SCAN CHANGES

McAdam and Robinson[19] reported a correlation of +0.79 between ratings of EEG change and clinical severity in dementia patients of mixed aetiology. The association between EEG slowing and severity of dementia has been replicated by many subsequent studies[4,6,20]. However, Johannesson *et al.*[12] report that this electroclinical relationship held for 100% of their AD cases but almost half of their Pick's and MID patients had normal EEGs in the presence of significant cognitive decline. The correlation between the EEG slowing and extent of cortical atrophy as measured by computed tomography (CT) is weak, the link being obvious only in advanced cases. The EEG correlates better with clinical scales sensitive to early dementia, while the converse is true for the CT scan[20]. Combining the two measures improves their diagnostic power. A discriminant function analysis study of 56 AD patients and 84 normal controls correctly classified 86% using the EEG data and 84% using the CT scan information. Combining the EEG and CT scan variables improved the correct classification rate to 90%[2]. Interestingly enough, the degree of functional brain impairment as measured by

the EEG predicts survival time while the extent of cortical activity does not[22].

THE APPLICATION OF QUANTITATIVE ELECTROENCEPHALOGRAPHY

Recent computerized EEG (CEEG) investigations have used frequency spectral analyses of the background activity and have generally replicated the earlier reports obtained by visual inspection of the EEG tracings. An overall slowing in mean EEG frequency is an invariable finding, with relative power increases in the slower frequencies (theta/delta) and decreases in the fast (beta) frequencies. The degree of frequency slowing correlates reasonably well with clinical ratings of dementia severity, e.g. Mini-Mental State and Clinical Dementia rating scales.

Is there a Relationship to Clinical Severity?

Alterations in the distribution of power across the various frequency bands seem to relate to the severity of the dementing process. In less severe cases, the main changes are increases in theta and reductions in beta power. When the disease is advanced, the respective amounts of delta and alpha power are also affected, the former being increased and the latter reduced. These associations have been observed during cross-sectional studies, there being a paucity of longitudinal investigations.

What About Early Cases?

Much of the work has been on populations of patients with established AD being cared for in hospital. A number of recent studies have examined mild probable AD patients (clinical dementia ratings of 1) compared to age-matched controls. These have replicated the earlier findings of frequency spectral slowing which have a specificity of virtually 100%[23]. However, the sensitivity is only 20%. This means that only one in five of early cases of AD will have CEEG findings that deviate three standard deviations from the mean and therefore fall into the AD range.

The Potential Role of Brain Mapping

A new development in EEG technology has been brain electrical activity mapping (BEAM). This involves sampling the cortical electrical activity from multiple scalp electrodes and calculating the distribution of voltage across the whole of the scalp using a mathematical interpolation method. The patterns of scalp voltage distribution are displayed as colour-coded contour maps. This technique investigates the patterns of electrical activity generated at the same time by different areas of cerebral cortex. It can be used to detect regional differences and promises to be a useful tool in the investigation of the dementias. Several investigators have used multichannel or BEAM recordings to demonstrate localized left temporal lobe delta power abnormalities, which may in AD patients be an early manifestation of the disease[24–27]. Hence, BEAM may prove especially useful in the early detection of dementia.

Does the CEEG Change as the Dementia Progresses?

The few longitudinal CEEG studies that have been carried out over several years give conflicting results. Some report significant decreases in mean frequency over time, with increases in delta/theta power and reduced alpha and beta activity[28–29], but others have found either statistically insignificant trends in the direction of frequency slowing or that only about half of AD patients show progressive EEG changes over 12 months[30–31]. It is noteworthy that the negative reports deal with relatively short time scales; 18 months or less. This may not be long enough to establish significant progression. There is also some evidence that frontal lobe quantitative changes may precede more generalized slowing[31].

Differences between AD and MID

Few CEEG investigations have investigated the question of quantitative differences between AD and MID patients. A recently completed study in my laboratory reveals significantly greater amounts of delta power and less alpha power in the temporal and parieto-occipital areas of both hemispheres in AD patients, compared to those with a clinical diagnosis of multi-infarct dementia. As well as having less alpha power, the peak alpha frequency is slower in AD patients with mean values of 7 Hz and 8 Hz in AD and MID subjects, respectively, and significant asymmetry between the hemispheres in the MID patients[31].

The degrees of synchrony between different areas of cortex within each cerebral hemisphere and between homologous areas of the right and left hemisphere can be assessed by coherence spectral analyses, which measures the similarity between pairs of EEG signals generated by different cortical areas. The coherence function is essentially a frequency correlation coefficient and measures the correlation at each frequency. It varies from 0 (signals quite different) to $+1.0$ (signals identical).

The main coherence differences between the AD and MID patient are seen in the temporal and parieto-occipital areas of both hemispheres. Compared to the MID patients, the within-hemisphere alpha and beta synchrony is lower in AD subjects. The pattern of between-hemisphere synchrony is different, being higher in AD patients for theta components between the temporal areas and lower for the alpha and beta frequencies between the parieto-occipital areas[31].

Do Elderly Patients with "Non-organic" Psychiatric Illness Deviate from Normals?

In my laboratory we have also investigated age-matched controls and elderly patients with major depressive illness. Compared to the normals, the depressive patients had significantly more theta power and less alpha power, such changes being maximal in the temporal regions. Indeed, the mean spectral values of the three patient groups could be ranked roughly according to degree of deviation from the healthy controls. The AD patients were the most deviant, then those with MID, and finally the depressed patients. The deviation of the elderly depressives from the healthy controls raises the issue of the contribution of organic brain disease to the genesis of affective disorder in old age, as suggested by current CT and single photon emission computed tomography (SPECT) scan work[32,33].

EVENT-RELATED POTENTIALS IN DEMENTIA

What is an Event-related Potential?

Event-related or evoked potentials (ERPs or EPs) consist of transient voltage changes that occur in response to a sensory stimulus. These take the form of a series of negative and positive

waves, which last a number of milliseconds (ms) and measure a few microvolts (μV) in amplitude. They are "buried" amongst the "noise" of the ongoing EEG and are "extracted" by summating or averaging the response to a series of identical stimuli. This results in a waveform that lasts from a few ms up to several s.

Types of Event-related Potential

It takes about 20 ms for information to reach the cerebral cortex from a peripheral sense organ. Hence the early ERP components reflect neuronal activity in the sensory receptor itself and the afferent pathways of the brainstem. They depend on the functional integrity of the relevant sensory system, being relatively impervious to changes in psychological state. The brainstem responses consist of five positive (I–V) waves within 10 ms of the stimulus, and are especially stable and stimulus-bound, having prolonged latencies in brainstem disease. In contrast, the middle-latency (80–200 ms) and long-latency ($>$200 ms) components are influenced by attention processes and how the subject perceives or processes the stimulus. The long-latency waves are termed cognitive or endogenous potentials, since their form is largely determined by the subjects' psychological state.

Healthy Ageing

The latency and waveform of sensory ERPs are critically affected by peripheral receptor changes. Hence, impaired hearing and visual acuity, common in the elderly, can cause problems in interpretation. If such sensory deficits are controlled for, the early and mid-latency potentials are little affected by healthy ageing. In contrast, the P_{300} wave, a positive going cognitive ERP that appears about 300 ms after a subject receives an important but unexpected stimulus, declines in latency and amplitude with advancing years.

Brainstem ERPs

Since there are brainstem changes, neuronal cell loss and neurofibrillary tangles in AD early ERP abnormalities can be predicted. The available brainstem auditory evoked response data are conflicting, two studies reporting delayed central conduction times (prolonged I–V intervals) with negative findings in a third[34–36].

Visual ERPs

A promising finding is the differential latency pattern of visual evoked potentials in dementia. Wright *et al.*[37] report completely normal pattern reversal responses with significant latency delay of the major positive component (P_2) of the flash response. The difference value between the prolonged flash P_2 latency and the normal latency value of the equivalent positive (P_{100}) wave of the pattern response is much longer in dementia patients compared to controls. It has the advantage of being little affected by drugs and only slightly lengthened by the ageing process, but does not discriminate between AD and MID[38]. These findings have been replicated twice[39,40].

Cognitive ERPs

The P_{300} wave is elicited by a task requiring discrimination between two types of stimuli, one frequent and the other rare in repetition. It develops as a response to the rare stimulus, which is used as a target and is a measure of cognitive processing time. Its latency may well reflect the time required for stimulus evaluation and categorization, while the amplitude is inversely related to probability of occurrence of the target stimuli. Healthy ageing increases the latency by around 1.36 ms/year and decreases the amplitude at a rate of about 0.18 μV/year[41]. The P_{300} latency is prolonged in many dementia patients by more than 1.5 standard deviations from the normal age-related mean and lengthens progressively over time[42,43]. Positron emission tomography (PET) scanning of early patients has shown that P_{300} latency is inversely correlated with the relative metabolic rates of the parietal and, to a lesser extent, temporal and frontal association areas, but not with the subcortical areas[44]. There is also a significant positive correlation between P_{300} amplitude and CSF 5-hydroxyindole-acetic acid (5-HIAA) concentration in AD patients[45].

Distinctions between Cortical and Subcortical Dementia

Some work suggests that auditory ERP patterns may be useful in distinguishing cortical from subcortical dementia. The P_{300} wave is abnormal in both. In contrast, the earlier waves (middle-latency components; N_1, P_2 and N_2) are intact in the former but abnormal in the latter[46]. Indeed, a recent preliminary study reports correlations with specific aspects of cognitive functioning; N_1 and P_2 with motor speed and N_2 with short-term memory[47].

OVERVIEW

The potential application of the ERP recordings to the diagnosis of dementia has yet to be clearly defined. None of the available techniques are capable of distinguishing between AD and MID. The visual flash-pattern reversal latency pattern is a robust finding in established cases of dementia of cortical origin. Further, there is some evidence that it reflects a specific cholinergic deficit. However, the abnormality rate in patients during the early stages of dementia remains to be determined. On the other hand, the P_{300} latency delay has been shown to be present in a majority of recent-onset AD patients[44]. A difficulty is that the correct classification rate for AD patients using the P_{300} data alone has varied widely across studies, from 89% to 20%, most having rates of more than 70%. This variability reflects not only differences in the clinical material and selection of controls but also the type and level of task difficulty of the experimental paradigm used to record the P_{300} wave. The paradigm has differed in the various studies. Research is required to determine the optimum paradigm for eliciting abnormality in early dementia cases, so that standardization across studies becomes possible. Further work on central brainstem conduction times and the pattern of middle latency components in subcortical dementia is also indicated.

Computed Tomography (CT)

Alistair Burns[1] and Godfrey Pearlson[2]

[1]*University of Manchester, UK, and* [2]*Johns Hopkins Hospital, Baltimore, MD, USA*

Computed tomography (CT) was introduced in the early 1970s and has become one of the standard investigations in the clinical neurosciences. In cranial CT, X-radiation is passed through the head in the form of a tightly collimated beam and is measured by a series of detectors. Radiation is absorbed by the intervening structures, which results in "attenuation" of the beam. Attenuation is maximal in high-density regions such as bone and minimal in low-density regions such as cerebrospinal fluid (CSF). The information from the detectors is processed by computer and the product is a numerical output. The brain is divided into three-dimensional volume elements (or voxels) and each is given an attenuation number, which represents the average attenuation in that area. The numerical output is transferred to a grey scale and each voxel is represented by a two-dimensional pixel. The familiar CT scan images are the result of the pictorial representation of the pixels on the grey scale. Areas of high attenuation are represented by white and areas of low attenuation by black. Areas with intermediate attenuation (such as brain substance) appear grey. The amount of radiation exposure in an average CT scan is slightly less than that in a set of conventional skull X-rays.

USE OF CT IN CLINICAL PRACTICE

CT has several advantages over magnetic resonance imaging (MRI) in the investigation of dementia. Acute haematomas can be easily distinguished from areas of infarction, the increased density of the former contrasting significantly with the hypodensity of the latter. In practice, CT is more widely available than MRI and the examination is less arduous and can be completed much faster. The presence of a cardiac pacemaker or the presence of surgical clips from previous brain surgery are not contra-indications to CT scanning in the same way that they are for MRI.

Guidelines have been published that suggest the circumstances under which a CT scan should be performed for the work-up of dementia[1,2]. Essentially, where the duration of the illness is short (<6 months and certainly <3 months), and where the features of the illness indicate that there may be cerebral pathology, then the chances of a CT scan detecting a clinically significant lesion is increased. Such features include: focal neurological signs; epileptic fits; variations in the course of the illness; and indicators of the presence of normal pressure hydrocephalus (gait disturbance, and incontinence in the presence of dementia). One study specifically examined a population sample aged 65+ and found that potentially treatable lesions (subdural haematoma, hydrocephalus, non-metastatic intracranial tumour) were present in 145 out of a possible 137 000 patient years at risk[33]. Specific features predicting the detection of such a lesion were: cognitive impairment for 1 month or less; head trauma in the week before mental state change; rapid onset of change over 48 h; history of CVA; seizures or incontinence; focal neurological signs; papilloedema; visual field defects; gait abnormalities; postural instability; or headaches. Paris *et al.*[3] estimate that the yield of potentially treatable conditions is about 3%. Factors on CT scan that predict who will respond positively to a CSF shunt have been documented by Vanneste *et al.*[4]—cerebral atrophy and the presence of white matter disease were poor predictors of response to the insertion of a shunt.

DIFFERENTIAL DIAGNOSIS

CT scanning is helpful in confirming certain diagnoses, e.g. Alzheimer's disease (AD), but is not the definitive investigation, whereas in other disorders, e.g. 'subdural haematoma' the CT is the definitive investigation.

The CT scan has been used to differentiate vascular dementia from primary degenerative dementia. Generally speaking, good concordance between the presence of vascular lesions on CT and the presence of vascular dementia (defined purely clinically or using the Hachinski score) has been achieved[5–7].

White matter lesions on CT scan have been widely reported[8,9] and are associated with impaired cognitive function (in both AD patients and non-demented subjects) and neurological signs (gait disturbance and extensor plantar response). Scheltens *et al.*[10] described a number of rating scales used to detect white matter changes on CT and MRI brain imaging, concluding that the ideal rating scale is not yet in existence but that different rating scales serve individual purposes.

Excessive ingestion of alcohol can result in cerebral atrophy and ventricular dilatation on CT scan, particularly affecting the frontal lobe and cerebellar vermis. It is apparent that the changes occur relatively early (but do not antedate alcohol excess), are apparent before any clinical evidence of declining cognitive function and may be partially reversible with abstinence[11]. There is also evidence that third ventricular size is correlated with memory impairment in alcoholics without Korsakoff's deterioration. Patients with Korsakoff's psychosis have more cortical atrophy and lateral ventricular enlargement, but the size of the third ventricle is particularly increased.

Depression has been shown to be accompanied by both cerebral atrophy and ventricular enlargement[12,13]. CT scan appearances in depressed patients appear to be midway between those of normal controls and demented subjects, tending to be nearer the latter. More recently, it has been shown that patients with reversible dementia secondary to depression (pseudodementia, or dementia

Table 63.1 Clinical and structural correlates on CT in AD

Reference	Mean age (or range)	*n*	CT measure	Clinical features	Association[†]
36	70.0	43	Cortex	GRD	C = 0.56

syndrome of depression) have CT scan changes such as increased lateral ventricular size and decreased tissue density numbers[14]. In paraphrenia, there is dilatation of the lateral ventricles, preservation of cortical structures and loss of the normal ventricular size/age correlation seen in normal ageing[15].

CT IN AD

Two areas of clinical interest are important in relation to CT scanning in AD. First, what is the diagnostic ability of the CT scan? Second, what CT changes take place in AD and how are they related to the clinical features of the disorder?

DIAGNOSTIC ABILITY OF CT

The second area of clinical interest relates to the ability of CT scan changes to differentiate patients with dementia from non-demented control subjects. It is well recognized that demented subjects can have normal CT scans, whereas normal subjects can have marked atrophic changes. Discriminant analyses are able to differentiate the two groups using CT scan appearances in about 80% of cases[16], a rate that has remained virtually constant over time in spite of advances in CT technology and methods of scan analysis[49]. In a meta-analysis, De Carli *et al.*[18] estimated sensitivity and specificity for a variety of CT measures. Specificity was high for most measures (about 90%, i.e. few normal subjects were classified as having abnormal CT appearances). Sensitivity (i.e. the number of AD patients regarded as having abnormal CT scans) was lower.

Serial CT scans in individual patients have been performed and have the potential for greater diagnostic accuracy. Increases in ventricular size have been shown to outstrip those which take place in normal ageing. Luxenberg *et al.*[19] found that the rate of lateral ventricular enlargement in male AD patients over 12 months completely differentiated these patients from controls (i.e. 100% sensitivity and 100% specificity). Increase in ventricular size correlates with deterioration in cognitive function[19] and two subgroups of patients with AD have been described on this basis of one with significantly increasing ventricular size and deteriorating cognitive function and one without these chages[20].

CLINICO–RADIOLOGICAL CORRELATIONS

Early studies demonstrated correlations between the degree of intellectual impairment and both cortical and subcortical atrophy on CT[21–23] but often included normal controls in the correlations. Normal control subjects tended to be patients referred for investigations and found to have normal scans, rather than people screened first and then scanned.

With regard to clinico-radiological changes, both cortical atrophy and lateral ventricular enlargement occur with normal ageing and tend to accelerate after the age of 60. There is a significant correlation between cerebral atrophy and age in normal subjects but this has not been as consistently found in dementia. Correlations have been described between cognitive function and both cortical atrophy and ventricular size. Generally, correlations are higher in the latter relationship (ventricular size can be measured as a continuous variable, which may partly explain the greater association), although some studies have reported no association between degree of dementia (measured by both specific cognitive tests and global ratings) and either CT measure. The third ventricle has been examined in a number of studies, and was found to be larger in demented patients than in age-matched controls, correlating with degree of cognitive impairment[17,24].

In addition to measures of global cerebral atrophy and ventricular enlargement, CT scans can provide other information of clinical interest. Regional cerebral atrophy has been shown to be related to certain behavioural disturbances[49]. Basal ganglia calcification is found in a significantly greater proportion of patients with delusions and demented patients with affective symptomatology have less severe CT scan changes, including relative preservation of the interhemispheric fissure[49].

Table 63.1 summarizes the relevant studies; 88% of ventricular measures show significant correlations with cognitive tests, whereas only 41% of cortical assessments do so ($\times 2 = 11.3$, $p < 0.001$, d.f. = 1).

The diagnostic potential of the specific temporal lobe views of the brain has attracted some interest in AD[25]. Pathologically, the temporal lobe discriminates well between AD and normal controls[26] and coronal plane CT images can be reformated to display the temporal lobes in fine detail.

CT has been combined with SPET (single-photon emission tomography) in order to improve diagnostic accuracy in AD. Jobst and colleagues, in the OPTIMA project in Oxford[27,28], reported a series of studies demonstrating that views of the temporal lobe could be achieved during CT scan, with the plane orientated along the long axis of the medial temporal lobe (20–25° anterior to standard CT angle). In this way, 92% of patients with AD were correctly diagnosed compared to a 5% false-positive rate. Simple measurement of the narrowest thickness of the medial temporal lobe (right or left) was about 50% thinner in patients with AD compared to controls. Combining these measurements with SPET in patients with histologically proven AD compared to controls, the medial temporal lobe atrophy provides 94% sensitivity and 93% specificity, parietotemporal hypoperfusion on SPET gave 96% sensitivity and 89% specificity, and the combination of both changes gave a sensitivity of 97%. The results of Lavenu *et al.*[29] who carried out a similar study using CT and SPET, resulting in a diagnostic accuracy rate which was much less—68%. Stage of disease is an important influencing factor in this rate and replication of the results of these studies is needed before they can be incorporated into clinical practice. O'Brien *et al.*[7] found reduced temporal lobe width in AD, vascular dementia and Lewy body dementia compared to controls, suggesting a lack of specificity of the finding with a single cross-sectional measurement.

CONCLUSION

In summary, the role of the CT scan in old age psychiatry is as a relatively non-invasive and widely available neuroradiological technique to exclude intracranial mass lesions. Regional changes may be helpful in the differential diagnosis of the dementia syndrome. The concordance between the CT changes and a clinical diagnosis of dementia is not absolute and significant overlap exists between the changes seen in dementia and those seen in normal ageing. Some methods of CT scan analysis are better than others in this differentiation and serial CT scans on individual patients may be an even better indicator.

Magnetic Resonance Imaging

K. Ranga R. Krishnan

Duke University Medical Center, Durham, NC, USA

The property that is the basis for magnetic resonance imaging is the interaction between hydrogen and a magnetic field. A hydrogen atom is a nuclear magnet which, when placed on the magnetic field, aligns itself in the direction of the field. In the process of aligning it develops a spin at a frequency which is called the Larmor frequency. If the magnetic field is varied, then the frequency of this oscillation also varies. Besides hydrogen, when a nucleus contains an odd number of either protons or neutrons, it is magnetic. As indicated earlier, the frequency of oscillation of hydrogen is proportional to the strength of the magnetic field. Resonance occurs when the applied frequency (magnetic frequency) is the same as that of the object. Magnetic nuclei in a magnetic field can be stimulated by other magnetic fields. These fields can usually be created by radio-frequency waves. When the radio-frequency waves are tuned to the Larmor frequency of the atomic nuclei, namely hydrogen, then the direction of oscillation of the atom moves towards the direction of the newly applied magnetic field. When the field is turned off, the nuclei relax, emit absorbed energy and return to the state prior to the radio frequency stimulation. This process can be repeated over and over again, provided that enough time is allowed for the relaxation of the atom. When consideration is given to an entire object composed of billions of atoms, the relaxation of these atoms will depend upon local effects, i.e. what molecule the atom is attached to, etc., the most common attachment being water for hydrogen. The signal detected when the hydrogen atom relaxes after the radio frequency and pulse has stopped can be detected by using a radio frequency antenna tuned to the Larmor frequency. The decay of this signal over time is called free induction decay. The time to recover two-thirds of the magnetization after stopping the radio-frequency stimulus is called the T1 relaxation time, or spin lattice relaxation time. This relaxation time is influenced by the environment of the hydrogen atom and can vary between gray matter, white matter, and fluid. T1 primarily refers to the longitudinal vector of relaxation, which is along the direction of the magnetic field. Another vector at right angles to the field, called the transverse vector, can also be measured, and its relaxation is called T2 relaxation. By convention, this refers to the time when it disappears, rather than the two-thirds used for measuring T1. T2 is always shorter than T1. Based on the properties of the longitudinal and transverse vector, one acquires images that are predominately T1-weighted, or those which are predominately T2-weighted, a third type that appear intermittent in appearance. In a T1-weighted image, fluid appears dark. In a T2-weighted image, fluid appears bright and white. Scanning sequences can be optimized by emphasizing one contrast vs. another. This allows a better distinction of both pathology and normal tissue.

MAGNETIC RESONANCE MORPHOMETRY

Magnetic resonance morphometry basically utilizes the acquired images to identify objects and then to quantitate their volumes. Volumes can be estimated in either two dimensions or three. The most common method of estimation is to use two-dimensional slices through a given object. A number of studies have indicated that systematic sampling is better than the randomized sampling of the particular object of interest. Segmentation of the object can be accomplished manually or by semi-automated means, and more recently in an automated fashion. Factors that effect the sensitivity and accuracy of the estimation of the volume include the number of slices that go through the object, the orientation of the slices, contrast, and any inhomogeneities in the magnetic field. Magnetic resonance morphometry methods have greatly improved over the last decade and are now widely utilized for studying a variety of neuropsychiatric disorders. The techniques, which were initially primarily manual outlining of an object, have vastly improved and now include semi-automated and automated techniques to estimate the volume of the object.

GERIATRIC PSYCHIATRY

The application of MRI in geriatric psychiatry has been extensive. There are two broad areas to which MR techniques have been applied. One is to evaluate the presence of gross pathology and the other is to evaluate morphemetric changes in a variety of disorders in the elderly. MRI is often utilized to look for tumors, infarcts, etc. when one suspects disease in a patient. MRI can detect space-occupying lesions and, given that images can be acquired in three dimensions, it can often provide better resolution than computed tomography (CT) (it must be kept in mind that newer forms of CT provide sufficiently high resolution). MRI is not useful in identifying calcifying objects, and in this particular case CT is far better. The use of contrast agents, such as gadolinium, can distinguish any breaking of the blood–brain barrier and often these agents are utilized to produce additional contrast of pathological tissue. Full-blown infarcts can be easily identified on MRI. In addition, MRI can be utilized to measure blood flow through large vessels, a technique known as called magnetic resonance angiography.

BRAIN ATROPHY

The second aspect as it relates to geropsychiatry is a measurement of brain atrophy and dementia. Patients with frontal temporal

dementia have significant atrophy of the frontal lobes. This can be easily visualized using MRI and quantitated if need be. Patients who have significant Alzheimer's disease (AD) will demonstrate observable hippocampal atrophy. Over time this can be measured and utilized for assessing the progression of the disease. MRI can be acquired with a different contrast, as noted earlier, and in three dimensions. Utilizing this one can develop specific methods to identify objects of interest and quantitate these objects. Fluid measurements of cerebrospinal fluid in different locations can also be easily measured. The technique also seems to be of particular use in mild cognitive impairment, in which commencing atrophy, especially of the hippocampus and temporal cortex, are often seen.

SILENT INFARCTS

Another area of growing interest in geropsychiatry is the identification of silent infarct or leukoencephalopathy. These are a function of aging. The risk factors are very similar to those of stroke, including high blood pressure, diabetes, etc. These changes are usually present in the deep white matter, the periventricular region, and subcortical nuclei such as the caudate putamen and thalamus. These silent strokes occur at the ends of the perforating blood vessels of the brain. These blood vessels do not have collaterals and are therefore more susceptible to the development of occlusions and the ischaemia that results from them. These silent strokes have been characterized pathologically as areas of myelin pallor, true infarcts (dead tissue and lacuna). A lacuna is distinguished by the presence of fluid inside the area and this can be determined by a bright signal on T2 and a dark signal on the T1 images. These changes have been related to depression, bipolar disorder and dementia. They are present in both AD and vascular dementia. The contributing role of these factors in AD is controversial. Epidemiological studies indicate that the presence and extent of these changes is a good indicator of a development of dementia and it has the same odds ratio as APO-E studies.

In summary, MRI is widely utilized to study various types of neuropsychiatric disorders. It has particular application and utility for identifying pathology and atrophy in the context of dementia, and lesions such as silent strokes in late-life depression and late-life bipolar disorder.

Functional Magnetic Resonance Imaging (fMRI)

K. Ranga R. Krishnan

Duke University Medical Center, Durham, MC, USA

Functional MRI (fMRI) is a new technique that has allowed the non-invasive assessment of physiological function of the brain in humans. The phenomena of nuclear magnetic resonance has been utilized to accomplish this. The first attempt at producing a functional image of the human brain utilized an invasive technique of evaluating blood flow changes in the brain, assessed by using a contrast agent. The non-invasive method was introduced by Ogawa, and is based on a blood oxygenation level-dependent contrast (BOLD) This contrast originates from the homogeneity induced by deoxy-haemoglobin in red blood cells. Signal intensities in MRIs are therefore acquired in a manner sensitive to this BOLD contrast, which is effected with regional deoxyhaemoglobin content. The rationale underlying the changes in deoxyhaemoglobin is that regional blood flow increases, while the oxygen consumption rate is not altered significantly, resulting in a lower deoxy-haemoglobin content per unit volume of brain tissue. The signal intensity in the image acquired sensitive to BOLD therefore increases in active regions relative to those regions which are not active.

Another technique that has been developed, called EPISTAR and FAIR, utilizes tagging of blood spins to measure cerebral blood flow changes. In a recent study, we have demonstrated that, using EPISTAR, there is a reduction in blood flow in the left frontal lobe in depressed patients. BOLD as well as FAIR can be developed and utilized in regular MRI 1.5 tesla scanners. However, many particularly exciting findings are emerging from high-field MRI, 4 tesla and greater. BOLD response is greater in a higher magnetic field, which produces an improved contrast.

APPLICATION OF fMRI

fMRI has been mostly utilized with the BOLD type of measure to evaluate brain regions involved in a task performance. Unlike positron emission tomography (PET), fMRI allows a single trial design and a single subject design and measures images that can be acquired in tenths of milliseconds, which is still much slower than the temporal response of neurons but similar to the response of the vascular system. In the design paradigms in general, the contrast is measured before and during a task and this can be done repeatedly to obtain an average within a subject on/off task. It can also be used to track the evolution of a particular task over time, that is the temporal evolution of the signal relative to the execution of this task can be obtained and averaged following repeated executions of the same task. It also allows evaluation of learning, errors, habituation, etc. The technique has had limited applicability so far to disease conditions, except as it relates to the evaluation of working memory tasks and other components of memory in patients with mild cognitive impairment, as a prelude to assessing whether they are likely to develop dementia over time. Clearly, this technique offers a significant possibility for understanding many of the neuropsychological functions that are altered in aging and acquiring the ability to assess their changes relative to particular diseases of aging.

Positron Emission Tomography (PET)

Peter F. Liddle[1] and Cheryl L. Grady[2]

[1]*University of British Columbia, Vancouver, British Columbia and* [2]*Rotman Research Institute, Toronto, Ontario, Canada*

Positron emission tomography (PET) provides quantitative images of the function of the brain in life. It generates an image of the distribution of a radioactively-labelled tracer substance that is distributed in the brain according to its pattern of physiological activity. By appropriate choice of tracer substances, it is possible to measure physiological variables such as blood flow, metabolism, neurotransmitter receptors, presynaptic neurotransmitter pools and aspects of amino acid metabolism.

The essence of any tomographic technique is a mathematical reconstruction of a two-dimensional image of the distribution of some physical variable (e.g. concentration of radioactivity), from a set of measurements of the value of that physical variable, averaged along a large number of intersecting straight-line paths through the brain. The feature that distinguishes PET from single photon emission computed tomography (SPECT) is the fact that a PET camera detects the paired photons generated by positron annihilation. When a positron is emitted from the tracer substance, it is annihilated by collision with an electron in the surrounding matter. This annihilation generates two γ-ray photons, which each have an energy of 511 keV and must travel in opposite directions. When two photons are detected simultaneously in different crystals arranged in a ring around the head, it can be concluded that a positron annihilation event has occurred at some point along the straight line connecting the two detectors. This use of coincidence detection of pairs of photons to determine the direction of travel of the photons is intrinsically more efficient than the use of collimators to determine the direction of travel, as is necessary in SPECT. Furthermore, correction for absorption in the brain tissue is straightforward in PET studies, because the amount of absorption along the straight-line path between a pair of detectors can be measured directly in a preliminary transmission scan, using a ring source. It is thus possible to quantify the local concentration of the positron-emitting isotope in the brain in absolute terms.

The positron-emitting isotopes used in PET are ^{15}O [half-life for radioactive decay (T/2) 2 min]; ^{13}N (T/2, 10 min); ^{11}C (T/2, 20 min); and ^{18}F (T/2, 110 min). The relatively short half-life of positron-emitting isotopes presents a logistic problem, since the PET camera must be located near to the cyclotron required to produce the isotopes. However, an advantage of short-lived isotopes is that the rapid decay of radiation minimizes unnecessary radiation exposure after the procedure is completed. In addition, in the case of ^{15}O, it is possible to carry out multiple separate PET scans within a single session of investigation, allowing the measurement of changes in brain function in response to various mental or pharmacological stimuli.

PET TRACER SUBSTANCES

In principle, virtually any substance involved in physiological processes that can be labelled with a positron-emitting isotope might be used in PET, but quantitative measurement requires an adequate mathematical model of the processes governing distribution of the substance in the brain.

An image of regional cerebral blood flow (rCBF) can be obtained from the distribution of intravenous [^{15}O]H_2O which is delivered to the brain at a rate depending on cerebral perfusion. Inhaled [^{15}O]oxygen provides an image of oxygen distribution in brain tissue which, when combined with an rCBF image, can be used to generate an image of regional oxygen metabolism ($rCMRO_2$). Intravenous [^{18}F]deoxyglucose (FDG) can be used to provide an image of regional glucose metabolism (rCMRGlu). This technique relies upon the fact that deoxyglucose is transported into cells by the same mechanism as is responsible for glucose uptake, but its metabolism is arrested after the first reaction in the glycolytic pathway. Hence, deoxyglucose accumulates within cells at a rate which reflects the rate of entry of glucose into the glycolytic pathway.

The development of labelled ligands that are suitable for measuring the characteristics of neurotransmitter binding sites is a difficult task, because of the difficulty in achieving a high level of specific binding at tolerable doses of the ligand. An example of a well-behaved ligand is [^{11}C]raclopride, which binds to D2 dopamine receptors[1]. It associates and dissociates rapidly from receptors, so that equilibrium is established relatively quickly, making it possible to determine an equilibrium binding curve. From such a binding curve, it is possible to determine the strength of binding (KD) and the density of receptors (B_{max}). Other ligands that have been used to study neurotransmitter function include [^{11}C]SCH 23390 for D1 dopamine receptors[2], [^{11}C]WAY-100635[3] to measure 5-HT_1 serotonin receptors, and [^{18}F]altanserin[4] and [^{18}F]setoperone[5] for measurement of 5-HT_2 receptors.

SOURCES OF VARIATION IN PET IMAGES

If an imaging technique is to be useful for delineating pathological processes, it is necessary that the variation in image due to the pathological process of interest should not be swamped by

variation arising from other factors. The difficulties in dealing with the multiple sources of confounding variation in PET images has hitherto limited the contribution of PET to the delineation of psychiatric disorders. From the clinician's viewpoint, the biological sources of variation are the most relevant, some of which are considered below.

In the study of elderly patients, one of the potentially confounding differences between subjects is brain atrophy, which is liable to produce variation in partial volume effects. Partial volume effects are due to the limited spatial resolving power of PET cameras, resulting in the contamination of the signal from high-intensity regions by adjacent tissue with low intensity. For example, if grey matter volume is reduced, the measured functional activity of the grey matter will be lowered by an increased contribution from adjacent white matter or CSF. A number of studies have examined the effect of cerebral atrophy on metabolic measures obtained with PET in both healthy older adults and patients with Alzheimer's disease[6,7]. A recent study by Ibanez *et al.*[8] used measures of grey matter volume obtained from MRI scans to correct PET FDG images in a group of mildly to moderately demented AD patients. They found that metabolic values in parietotemporal and frontal cortex were reduced compared to a control group, even after correction for atrophy. These data suggest that, despite the undoubted contribution of partial volume effects, the metabolic deficits seen in these patients are not due simply to atrophy, but reflect true decreases in metabolic activity.

When evaluating images of brain function, it is necessary not only to be aware of confounding variance introduced by extraneous factors, but also to know that the functional impairments in a single disease are quite heterogeneous. For example, the clinical manifestations of AD are diverse, including not only impairments of memory but also many different aspects of cognitive function and behaviour. In accord with this behavioural heterogeneity, PET studies reveal that cases differ in the degree of laterality of the abnormalities, and also in the degree of frontal involvement[9]. On the other hand, different diseases can produce phenomenologically similar mental states, raising the possibility that different diseases might produce similar patterns of perturbation of regional blood flow and metabolism. This possibility is illustrated by the fact that hypometabolism of frontal cortex has been reported in AD[9], depression[10], Parkinson's disease[11] and in the psychomotor poverty syndrome in schizophrenia[12]. The greatest value of PET thus may lie in the sensitive measurement of particular patterns of brain malfunction, rather than the distinction between diseases differing in aetiology.

ACTIVATION STUDIES

A potentially useful approach to the measurement of brain function is within-subject comparison of brain activity during behavioural or pharmacological activation with that in an appropriate reference state. Behavioural activation has been used to identify the brain areas involved in specific mental activities in healthy young adults[13,14] and in older individuals[15]. Interestingly, older adults have been found to have greater activation in frontal areas during some types of cognitive activity, compared to younger adults[16,17]. These results have led to the suggestion that frontal cortex may play a compensatory role in the face of reduced function in other task-relevant brain areas, an idea that also is relevant to diseases of ageing.

Measurement of rCBF during pharmacological activation allows measurement of the response of the brain to drugs that alter neurotransmission. Although not yet used in psychiatric populations, the feasibility of this type of strategy has been demonstrated in normal subjects. For example, Friston *et al.*[18] demonstrated that buspirone (a partial agonist at serotonergic 5-HT_{1A} receptors) caused an attenuation of the normal increase in rCBF in the parahippocampal gyrus produced by a verbal memory task, as well as a transient impairment of memory test performance. Conversely, Furey *et al.*[19] have shown improved performance and reduced activity in the frontal lobe during a working memory task after administration of physostigmine, a cholinesterase antagonist. These studies suggest that modulation of neurotransmitter systems has specific effects on brain function during cognitive activity, and have interesting implications for the use of pharmacologic modulation in understanding psychiatric disorders.

BLOOD FLOW AND METABOLISM IN AD

PET studies have produced a moderately consistent picture of the abnormalities of blood flow and metabolism in AD. The most common pattern is bilateral reduction in parietal and temporoparietal flow and metabolism, especially in early cases[9,20,21], but the patterns of flow and metabolism show considerable variation between patients[22]. These variations correlate with variation in behavioural and neuropsychological impairments[9]. Longitudinal studies have demonstrated that focal metabolic abnormalities are detectable before the corresponding neuropsychological impairment becomes apparent, and that the metabolic abnormalities progress as the disease progresses[23]. Recent studies have shown that metabolic abnormalities similar to those seen in the cortex of AD patients can be found in asymptomatic persons at risk for familial AD[24] and that these deficits are associated with the presence of the APOE-4 allele[25].

A few activation experiments with AD patients also have been conducted. Mildly demented AD patients have shown greater frontal activations, compared to healthy elderly, during memory tasks[26,27] and during perceptual tasks[28]. This is similar to the increased frontal activity seen in the healthy elderly, compared to young adults, and indicates that recruitment of cognitive resources mediated by frontal regions may be a common response to a decline in brain function, whether caused by normal ageing or by disease.

BASAL GANGLION FUNCTION IN HUNTINGTON'S DISEASE

The major neuropathological process in Huntington's disease (HD) is degeneration of the basal ganglia, especially the corpus striatum. Hence, it would be expected that there would be a loss of postsynaptic D1 and D2 dopamine receptors in the striatum, which has been amply demonstrated with imaging of these receptors using [^{11}C]SCH 23390 and [^{11}C]raclopride, respectively[29]. It has been shown that a striatal decrease in dopamine is detectable even in asymptomatic persons who carry the HD gene mutation[30], and further that the degree of reduction is correlated with reduced performance on cognitive tests of frontal lobe function[31]. Glucose metabolism is also reduced in the striatum of HD patients and patients at risk for HD[32]. Longitudinal studies of disease progression in HD have shown declines in both striatum and frontal lobe metabolism[33], indicating that PET could be useful in following the effects of treatment over time.

Only a few activation studies have been carried out with HD patients. Patients have been studied with [^{15}O]water during hand or finger movements and show reduced flow in the striatum, motor areas and prefrontal cortex[34,35]. Of particular interest is that activity in parietal cortex in one study[34] was increased relative

to control subjects, suggesting a compensatory role of this region, similar to that postulated above for AD patients.

GERIATRIC DEPRESSION

Depression is a serious problem in older adults, and can occur as a symptom of a dementing illness or in the absence of dementia. The most common neuroimaging finding in depression is reduced glucose metabolism or flow in prefrontal cortex, although cingulate and paralimbic regions also are involved in mood disorders[36,37]. These regional patterns of reduction are seen in elderly as well as younger patients, although elderly depressed individuals are more likely to have global metabolic reductions in metabolism[38]. There is considerable evidence that the serotonergic neurotransmitter system is altered in depression[39] and ligands for measuring these receptors have recently been developed. A few studies have used PET to examine levels of serotonin receptors in depressed patients, but have reported conficiting results. In one experiment, 5-HT_2 binding was reduced in orbitofrontal areas in depressed patients[40], but no differences between depressed patients and controls were found in another study[41]. In older healthy adults 5-HT_2 receptor binding is reduced compared to young adults[42], but is not further reduced in elderly depressed patients. However, serotonin binding is reduced in AD patients[43], indicating that results from studies of geriatric depression should be viewed with caution, as they may have been influenced by coexisiting dementia, which is difficult to rule out clinically[39]. It is clear that much work in this area remains to be done, including the assessment of brain function during serotonergic challenge in the elderly.

CONCLUSION

The accumulating evidence that detectable changes in brain function precede structural changes in neurodegenerative conditions and, in addition, that PET can provide a measure of severity of disordered brain function, indicates the potential value of PET in early detection and in monitoring the effects of treatments intended to modify the progression of these conditions. One important contribution of PET to the investigation of geriatric disorders will likely be in its use to delineate the mechanisms of disordered cerebral function. In addition, the use of pharmacological challenges and the measurement of neurotransmitter function hold promise for our understanding of neuropsychiatric disorders in the elderly.

Single-photon Emission Computerized Tomography (SPECT)

Mohammed T. Abou-Saleh[1] and D. P. Geaney[2]
[1]*St George's Hospital Medical School, London, UK, and* [2]*Warneford Hospital, Oxford, UK*

The introduction of single-photon emission computed tomography (SPECT) has markedly enhanced the study of brain function. The development of SPECT was the culmination of a series of investigations of cerebral blood flow (CBF) pioneered by Kety and Schmidt[1] in the late 1940s, combined with the introduction of transmission computed tomography (CT) in the early 1960s, in which three-dimensional images are derived from two-dimensional data. This chapter provides a review of the principles and basic techniques of SPECT, its present utility and application to clinical practice.

PRINCIPLES AND TECHNIQUES

Kety and Schmidt[1] pioneered CBF studies in man using nitrous oxide as a diffusible agent. These early studies required inhalation of nitrous oxide and sampling of arterial and internal jugular venous blood and could only provide a measure of whole-brain blood flow. Techniques to measure regional rCBF followed and used freely diffusible radionuclides, such as ^{85}krypton and ^{133}xenon, which were injected into the carotid artery[2]. ^{133}Xenon emits γ-radiation, which can be detected through the intact skull, and multiple scintillation probes allow the measurement of CBF in specific regions of the brain. Further technological advances in detector sensitivity and data analysis allowed the replacement of intra-arterial injections by intravenous infusions or inhalation of gaseous ^{133}Xe, so that the measurement of rCBF became a non-invasive procedure. The rCBF data were initially presented in two dimensions and essentially reflected cortical flow, but with the development of the tomographic technology for SPECT, a three-dimensional measurement of rCBF could be obtained. The radiotracers used in SPECT emit a single γ-ray (or photon), as opposed to the dual simultaneous γ-rays of PET radiotracers, and hence the term "single-photon".

Recently, new radiotracers labelled with ^{123}iodine and ^{99m}technetium have been introduced. These lipophilic radiopharmaceuticals cross the blood–brain barrier and distribute in proportion to the rCBF shortly after intravenous injection. They are trapped in the brain and have a stable or static distribution over time, unlike freely diffusible, dynamic radiotracers such as ^{133}Xe, enabling images of higher resolution to be obtained. These agents can be used with the conventional rotating γ-cameras that are widely available in most nuclear medicine departments, whereas ^{133}Xe-labelled agents are not. The most advanced SPECT systems are now capable of a resolution of 8 mm and imaging times as short as 2–3 min for rCBF.

Unlike PET, there is no current prospect of SPECT being able to provide a direct measure of regional cerebral metabolism. However its use to measure neurotransmitter receptors is an evolving technique. The radioligand ^{123}I,3, quinuclidinyl 4-iodobenzilate (QNB) has been developed for the measurement of muscarinic acetylocholine receptors and has been applied to the study of Alzheimer's disease[3].

NORMAL SUBJECTS AND NORMAL AGEING

Dynamic tomographic studies with ^{133}Xe produce similar values for grey matter flows as found with PET, but substantially overestimate white-matter rCBF and consequently give a limited distinction between grey and white matter. Static tomographic studies with ^{123}I- and ^{99m}Tc-labelled radiotracers cannot, as yet, provide an absolute measure of rCBF, but the pattern of rCBF, which can be expressed semiquantitatively, is similar to that found in PET studies, and the resolution is better than with ^{133}Xe dynamic tomographic studies.

The pattern of rCBF reported in normal subjects reflects, at least in part, the conditions of the subjects at the time. For example, if subjects are studied with eyes open, the visual cortex has the highest individual rCBF, but if the eyes are closed, the rCBF is reduced[4]. At present there are no generally accepted standard conditions for the control or resting state but it is clear that these should be standardized in any individual study.

CBF is reduced in relation to both advancing age and progressive cerebrovascular disease, and hypertension is the most important predisposing factor for a significant reduction in CBF.

The reduction in rCBF with age is confined to the grey matter—the white matter is unaffected and is more marked in anterior cortical regions. Females have higher rCBF than males for subjects up to 60 years of age, but the difference lessens above this age.

In the normal individual at rest, the rCBF is closely coupled to the regional metabolism of glucose and oxygen and is felt to reflect the underlying cerebral function. PET studies have shown that during visual stimulation, the rCBF and metabolic rate of glucose have similar marked focal increases in the visual cortex, while the regional cerebral metabolic rate of oxygen has a much smaller increase[5]. This uncoupling of glucose uptake and oxygen metabolism suggests that most of the extra glucose taken up during physiological stimulation is not oxidized and presumably lactate production by glycolysis increases. The implication of

these findings is that in normal resting individuals, rCBF and the regional cerebral metabolic rate of oxygen or glucose will provide similar information about the underlying cerebral function, but when physiologically (or perhaps pharmacologically) stimulated, they may convey information about different aspects of cerebral function, with none being an index of cerebral function. Similarly, in pathological cerebral conditions, close coupling of rCBF and the cerebral metabolic rates of glucose and oxygen cannot automatically be presumed to be retained.

STUDIES IN DEMENTIA

In addition to the effects of normal ageing, functional imaging studies in dementia have three further problems: (a) the normal variation in measures of cerebral blood flow or metabolism; (b) uncertainty of diagnosis of type of dementia (e.g. Alzheimer's disease (AD) or multi-infarct dementia (MID))—AD accounts for over 50% of cases, and can only be diagnosed definitively by cerebral biopsy or at autopsy; (c) the presence of cerebral atrophy. However, some demented individuals have little atrophy, while some normal subjects show considerable atrophy. Consequently, areas of apparently reduced rCBF in patients with dementia may be due to reduced flow to a normal volume of brain, normal flow to a reduced volume of brain or reduced flow to a reduced volume of brain.

The studies by Kety and Schmidt[1] indicated lower rates of mean CBF in patients with dementia than in normal subjects, and most subsequent studies have confirmed these findings. Whole-brain studies have suggested that coupling between CBF and the cerebral metabolic rates of oxygen and glucose is present in the later stages of dementia, and although the link between CBF and the metabolic rate of oxygen is apparent in the early stages also, the metabolic rate of glucose is dissociated from these, such that it is relatively decreased in AD but increased in MID[6].

The use of SPECT to study dementia has been reported since the mid-1980s. Using the ^{133}Xe inhalation technique, Bonte *et al.*[7] found that out of 24 patients with probable AD, 19 had perfusion deficits, which were most commonly found in the parietotemporal flow, but instead had a patchy distribution pattern. However, ^{133}Xe SPECT involves measuring temporal variations in activity and is only possible with purpose-built equipment. The image characteristics are relatively poor because of scatter of the low-energy γ-rays and low counts obtained over the brief scanning periods.

The radiopharmaceutical ^{123}I-iodoamphetamine (IMP) does not present these technical problems and its initial cerebral uptake is proportional to rCBF. It was the first tracer to be

Table 67.1 ^{99m}Tc-HMPAO SPECT studies in dementia

Study	Patients (*n*)	Normal controls	Diagnosis	Assessment of images	Results
Neary *et al.* (1987)[11]	AD (23) FLD (9) PSP (9)	None	Clinical, NINCDS–ADRDA, CT scan	Qualitative	AD: posterior Cr Cerebral abnormalities, FLD and PSP anterior Cr abnormalities
Perani *et al.* (1988)[25]	AD (16) early	16	NINCDS–ADRDA, CT scan/MRI neuropsychology	Semiquantitative ratio of ratio of ROI to cerebellum	Decreased rCBF in frontal and temporo-parietal areas, hemisphere asymmetry
Burns *et al.* (1989)[26]	AD (20)	6	NINCDS–ADRDA, CT scan, psychometry	Semiquantitative ratio of ROI to cerebellum	Decreased rCBF in temporal and posterior parietal areas, regional rCBF correlations with memory, praxis and language functions
Gemmell *et al.* (1987)[10]	AD (17) MID (10)	3	DSM-III, Hachinski, MRI	Qualitative	Perfusion defects (temporoparietal occipital) more common in AD than MID, more bilateral defects in AD than MID
Battistin *et al.* (1989)[27]	AD (21) Mixed (9)	None	DSM-III, CT Scan	Semiquantitative ratio of ROI to cerebellum	Decreased rCBF (parietal) in AD than mixed AD and MID form, few showed right–left asymmetry
Goldenberg *et al.* (1989)[17]	AD (23)	None	Clinical CT scan neuropsychology tests	Semiquantitative ratio of ROI to all ROIs	Co-variation of neuropsychology test results with frontal inferior parietal and superior temporal regions
Podreka *et al.* (1987)[28]	Dementia (12)	None	CT scan	Semiquantitative (region/ whole brain)	All patients showed perfusion defects
Upadhyaya *et al.* (1991)[24]	AD (15)	10	NINCDS–ADRDA Geriatric Mental State, CAMCOG	Qualitative, semi-quantitative (ROI/ cerebellar)	All AD patients showed perfusion defects Significantly low ratios in parietal, frontal and occipital areas.
Jobst *et al.* (1998)	Dementia (200) Annual evaluation to necropsy	119	NINCDS-ADRDA DSM-IIIR	Semiquantitative	AD had medial temporal lobe atrophy (CT Scan) and parietotemporal hypo-perfusion. Both markers had better diag-nostic accuracy than NINCDS-ADRDA and DSM-IIIR.
Shih *et al.* (1999)	AD (18) Repeated 5–23 months	None	MMSE	Semiquantitative	All AD had decreased CBF in consecutive SPECT
Defebvre *et al.* (1999)	DLB (20) AD (20) PD (20)	None	MMSE	Semiquantitative	DLB: frontal CBF lower than AD
Mullet *et al.* (1999)	AD (116)	20	DSM-IIIR MMSE	Semiquantitative	3 regions with decreased CBF AD: 48% Controls: 10%

widely used in static SPECT studies of dementia. These have generally reported that patients with AD have deficits in flow which are maximal bilaterally in the parietotemporal cortex, while patients with MID vary from having a normal pattern to marked asymmetrical focal deficits anywhere in the cortex. Sharp *et al.*[8] found that, despite having characteristic regional abnormalities on SPECT, the majority of patients with AD had a normal appearance in those regions on magnetic resonance imaging (MRI). Ebmeier *et al.*[9] found that while MRI was not able to differentiate between AD and MID, 19 out of 21 patients showed bilateral deficits on IMP SPECT scans. Although the distribution of ^{123}I-IMP initially reflects the rCBF, redistribution of the tracer occurs approximately 1 h after injection. The use of ^{123}I-IMP is also limited by the restricted availability of ^{123}I, which has a half-life of 13 h, and is costly to produce, as this requires a cyclotron.

^{99m}Tc-HMPAO SPECT

^{99m}Technetium is readily available from commercial generators in nuclear medicine departments, is inexpensive and has a shorter half-life (6 h) and better dosimetry than ^{123}I. Labelling with ^{99m}Tc is a much more complex procedure than with ^{123}I and the development of a ^{99m}Tc-labelled compound to provide a measure of rCBF was a major advance in SPECT technology. Technetium-labelled hexamethyl propylenaemine oxime (HMPAO) is a lipophilic tracer which, after intravenous administration, crosses the blood–brain barrier with high extraction and is retained in the brain in hydrophilic form. The brain uptake occurs over the first 2 min and has a stable distribution for many hours. This enables conventional equipment to be used to detect the radiation emitted from the brain. Comparative studies with PET in humans reveal a tendency to underestimate flow in areas of high rCBF but a good correlation with areas of low and medium rCBF. Although ^{99m}Tc-HMPAO cannot, at present, be used to quantify rCBF absolutely, the results can be expressed semi-quantitatively by comparing the counts in each brain region of interest (ROI) to a reference area, such as the whole brain or cerebellum.

A number of SPECT studies have now been performed using ^{99m}Tc-HMPAO to investigate dementia and the characteristics of these are shown in Table 67.1. The studies varied in the populations studied, diagnostic criteria used and the methods of assessment of images. Some of these studies had no data on control subjects for comparison. The majority carried out initial screening with CT or MRI to exclude structural lesions.

The early studies used qualitative assessment of the images and found that most patients with AD had bilateral parietotemporal deficits; those who did not tended to be less impaired cognitively[10].

Frontal deficits were also seen in AD. Deficits were less common in MID than AD, particularly when known infarcts on MRI were excluded, and they occurred in a more variable and asymmetrical pattern. Neary *et al.*[11] also investigated patients with progressive supranuclear palsy (PSP) and others with the clinical syndrome of dementia of frontal-lobe type, which is consistent with, although not necessarily diagnostic of, Pick's disease.
